Theoretically correct equations, involving concentrations only, are established.

2.—Theory and Properties of the Salt Solution.—We are indebted to Landolt and Börnstein* for the most complete tables of the densities of salt solutions of different percentages up to saturated solutions at temperatures varying from 0° to 80° cent. These tables, therefore, will be taken as the basis for the development of the theory of the salt solution as applied in the chemical method for measuring quantities of water.

As the theory which is to be presented concerns largely the concentrations of various solutions, it will be convenient to elaborate on the tables to some extent by appending a column of concentrations. It will frequently be convenient to know also the quantity, either by volume or by weight, of distilled water or of salt, contained in a solution of given concentration. Therefore, additional columns, for these and similar purposes, are appended, so as to furnish the data in Table 1, which data are limited to temperatures between 0° and 40° cent.

3.—Approximate Formulas for Weak Solutions.—As Table 1 does not extend to salt solutions of less than ½ of 1%, several equations have been devised for computing densities in terms of concentrations, or percentages, and *vice versa*. These equations are merely approximate, but cannot be far from correct, especially as regards relative errors in computing densities. The general equation for density, d_x, at temperature, x, in terms of the density, d, of distilled water, at temperature, x, and one parameter, n, depending on the temperature, is,

$$d_x = d + n_x p_x \left\{ \begin{array}{c} \text{Limited to solutions of less than } \tfrac{1}{2}\% \\ \text{in salt} \end{array} \right\} \quad \ldots\ldots\ldots\ldots (1)$$

TABLE 1.—ONE LITER OF SALT SOLUTION, OF VARYING DENSITY, AT DIFFERENT TEMPERATURES.

TEMPERATURE = 0° CENT.

Volume of 1 Gramme of Distilled Water = 1.000132 c.c.

Percentage of salt solution.	Density, in grammes per cubic centimeter.	Concentration, in grammes per liter.	Weight of distilled water per liter of solution, in grammes.	Volume of distilled water per liter of solution, in cubic centimeters.	Apparent volume of salt per liter of solution, in cubic centimeters.	Salt per cubic centimeter of apparent volume, in grammes.	Apparent volume occupied per gramme of salt, in cubic centimeters.

TABLE 1.—(*Continued.*)

TEMPERATURE = 20° CENT.

Volume of 1 Gramme of Distilled Water = 1.001773 c.c.

Percentage of salt solution.	Density, in grammes per cubic centimeter.	Concentration, in grammes per liter.	Weight of distilled water per liter of solution, in grammes.	Volume of distilled water per liter of solution, in cubic centimeters.	Apparent volume of salt per liter of solution, in cubic centimeters.	Salt per cubic centimeter of apparent volume, in grammes.	Apparent volume occupied per gramme of salt, in cubic centimeters.

By determining the values of n for the various temperatures and then inserting these values in Equation (1) along with those of d for distilled water, there may be derived,

$$\left.\begin{aligned} d_0 &= 0.999868 + 0.772\,p_0 \\ d_{10} &= 0.999727 + 0.740\,p_{10} \\ d_{15} &= 0.999126 + 0.730\,p_{15} \\ d_{20} &= 0.998230 + 0.720\,p_{20} \\ d_{40} &= 0.992240 + 0.690\,p_{40} \end{aligned}\right\} \text{Limited to solutions of less than } \tfrac{1}{2}\% \text{ in salt} \quad \ldots\ldots(2)$$

which, for percentages, may be rewritten as follows:

$$\left.\begin{aligned} 100\,p_0 &= 129.53d - 129.52 \\ 100\,p_{10} &= 135.14d - 135.10 \\ 100\,p_{15} &= 136.99d - 136.87 \\ 100\,p_{20} &= 138.89d - 138.64 \\ 100\,p_{40} &= 144.93d - 143.80 \end{aligned}\right\} \text{Limited to solutions of less than } \tfrac{1}{2}\% \text{ in salt} \quad \ldots\ldots(3)$$

There may also be written:

$$\left.\begin{aligned} d_0 &= 0.499934 + \sqrt{0.249935 + 0.000772\,C} \\ d_{10} &= 0.499864 + \sqrt{0.249865 + 0.000740\,C} \\ d_{15} &= 0.499563 + \sqrt{0.249565 + 0.000730\,C} \\ d_{20} &= 0.499115 + \sqrt{0.249116 + 0.000720\,C} \\ d_{40} &= 0.496120 + \sqrt{0.246135 + 0.000690\,C} \end{aligned}\right\} \text{Limited to solutions of less than } \tfrac{1}{2}\% \text{ in salt.} \quad \ldots(4)$$

in which C is the concentration.

4.—For purposes of engineering and computation, a diagram plotted to a convenient scale will greatly facilitate determinations of the values of the quantities involved in Table 1 and the foregoing formulas without the necessity for calculations and interpolations. Plate XXXIII exhibits this plotting, the scale being sufficiently large to enable a reading of density to be made with great precision. This diagram, however, is not so accurate when it is required to ascertain the value of the concentrations of salt solutions in terms of the percentage. In order to ascertain concentrations with a sufficient degree of accuracy, Plates XXXIV and XXXV have been specially prepared. These diagrams give the relation between percentage and concentration with a high degree of precision when the temperature is between 10 and 30° cent., and may be used even beyond these limits. It is scarcely neces-

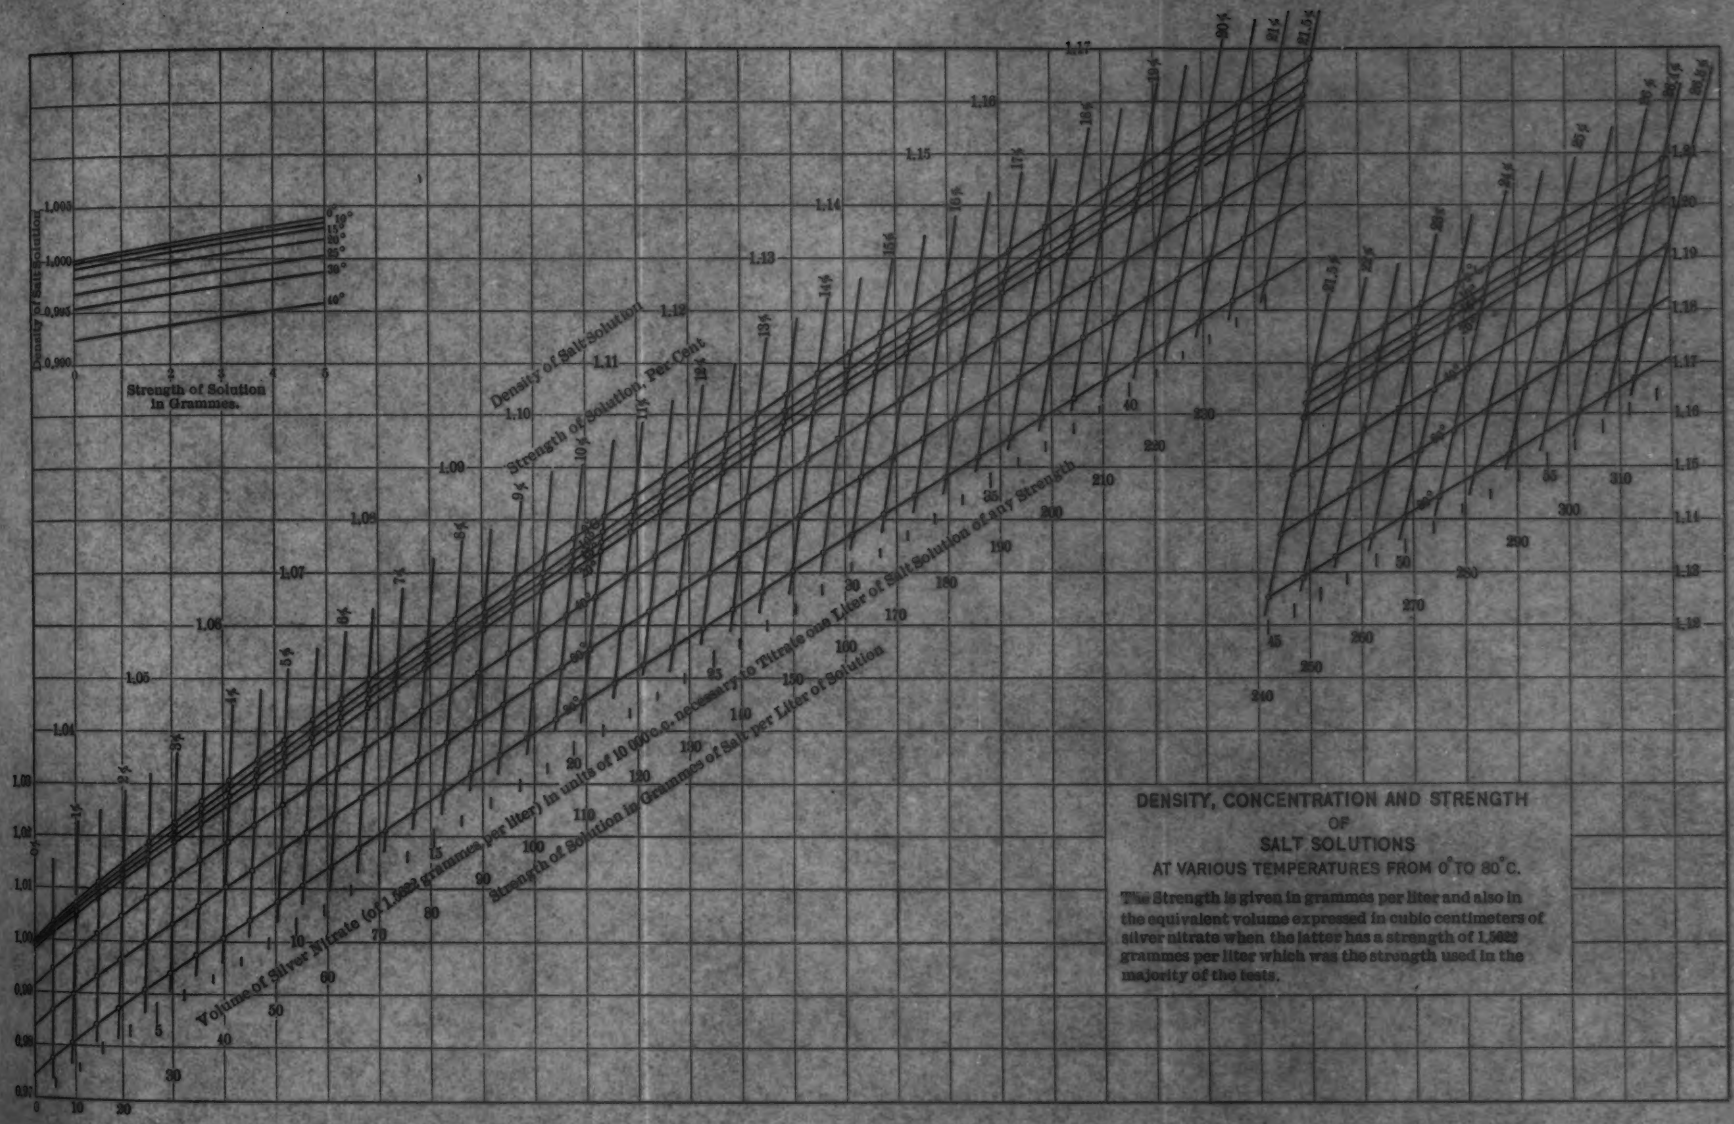
CHEMI-HYDROMETRY.



DENSITY, CONCENTRATION AND STRENGTH OF SALT SOLUTIONS AT VARIOUS TEMPERATURES FROM 0° TO 80° C.

The Strength is given in grammes per liter and also in the equivalent volume expressed in cubic centimeters of silver nitrate when the latter has a strength of 1.5822 grammes per liter which was the strength used in the majority of the tests.

sary to make any further explanation, as the plotting will be sufficiently well understood.

5.—*Volumetric Shrinkage.*—When two salt solutions of different densities are mixed, the volume of the resultant mixture is less than the sum of the volumes of the two components before mixing. Table 1 and Plates XXXIII, XXXIV, and XXXV show this, as illustrated by the following example, the figures for which have been taken from Table 1:

Of a ¼% solution, 100 liters are mixed with 1 liter of 25% solution at 20° cent. Find the percentage of the mixture, the density, and final volume, at the given temperature.

Solution:

	Kilogrammes of solution.	Kilogrammes of NaCl.
1 liter, 25% solution.....	1.1879	0.29698
100 liters, ¼% solution.....	100.19	0.50095
Totals	101.3779	0.79793

$$\text{New percentage of the mixture} = \frac{0.79793}{101.3779} = 0.78708.$$

The density for this percentage is 1.0039.

Therefore the final volume of the mixture is 101.378 ÷ 1.0039 = 100.984. Thus, the shrinkage of volume is 101 − 100.984 = 0.016 liter.

This illustration shows that there is a shrinkage of volume, and that, for a ratio of mixture of 100 to 1, the relative shrinkage is very small.

Take another case, where the ratio of mixture is, say, only 1 to 1. Let 1 liter of 25% solution be mixed with 1 liter of distilled water at 20° cent. Find the percentage of the mixture at the given temperature.

Solution:

	Kilogrammes of solution.	Kilogrammes of salt.
1 liter, 25% solution.....	1.1879	0.29698
1 liter, distilled water.....	0.9982	0.00000
Total weight	2.1861	0.29698

New percentage = 0.29698 ÷ 2.1861 = 13.585

Corresponding density = 1.0975 (Table 1).

Resulting volume = 2.1861 ÷ 1.0975 = 1.99189

Thus, the shrinkage of volume is 2 − 1.992 = 0.008 liter.

Although this result is less than the former one, the relative error is much larger, being about 0.4% of the entire volume and 0.8% of the volume of the distilled water with which the strong solution was mixed. In this case the error is also 0.8% of the volume of the strong salt solution which is diluted with the distilled water.

These illustrations point to the fact that the shrinkage is not great, but may be sufficiently large to be taken into account when errors of less than 1% are to be computed.

6.—Chemi-Hydrometry.—As the method of measuring quantities of liquids by chemical procedure has not yet received a distinctive name, it may be appropriate to suggest one. The word "Chemi-hydrometry" seems to describe very exactly the nature of the process, but has three features which seem to be more or less unfavorable to its adoption.

The word seems to be too long to recommend itself. It is a compound of words derived from different languages, which is not good form. The last component has been used almost exclusively in reference to determinations of density and specific gravity, and is not so well known as relating to measurements of quantities of liquids.

However, until a better name is suggested, Chemi-hydrometry will be used by the writer as referring to the body of rules, formulas, and processes connected with the measurement of quantities of liquids by chemical processes.

7.—Mixtures of Solutions.—When two salt solutions of different percentages are mixed at a given temperature, the mixture, when at the same temperature, will not have a volume equal to the sum of the two volumes mixed, but will be more or less deficient. In consequence of this shrinkage of volume, it is necessary to develop a theory of mixtures before volumes can be determined by chemi-hydrometry with certainty.

By "ratio of mixture" is meant the ratio of the quantity of the weaker of two solutions to the quantity of the other with which it is mixed. These quantities may be measured in units of volume or units of weight, according to circumstances or convenience. The symbol for this ratio will be f for units of weight, and r for units of volume.

By "ratio of dilution" is meant the ratio of the quantity resulting from the mixture of two salt solutions of different percentages to the quantity having the higher percentage which has been mixed with

PLATE XXXIV.

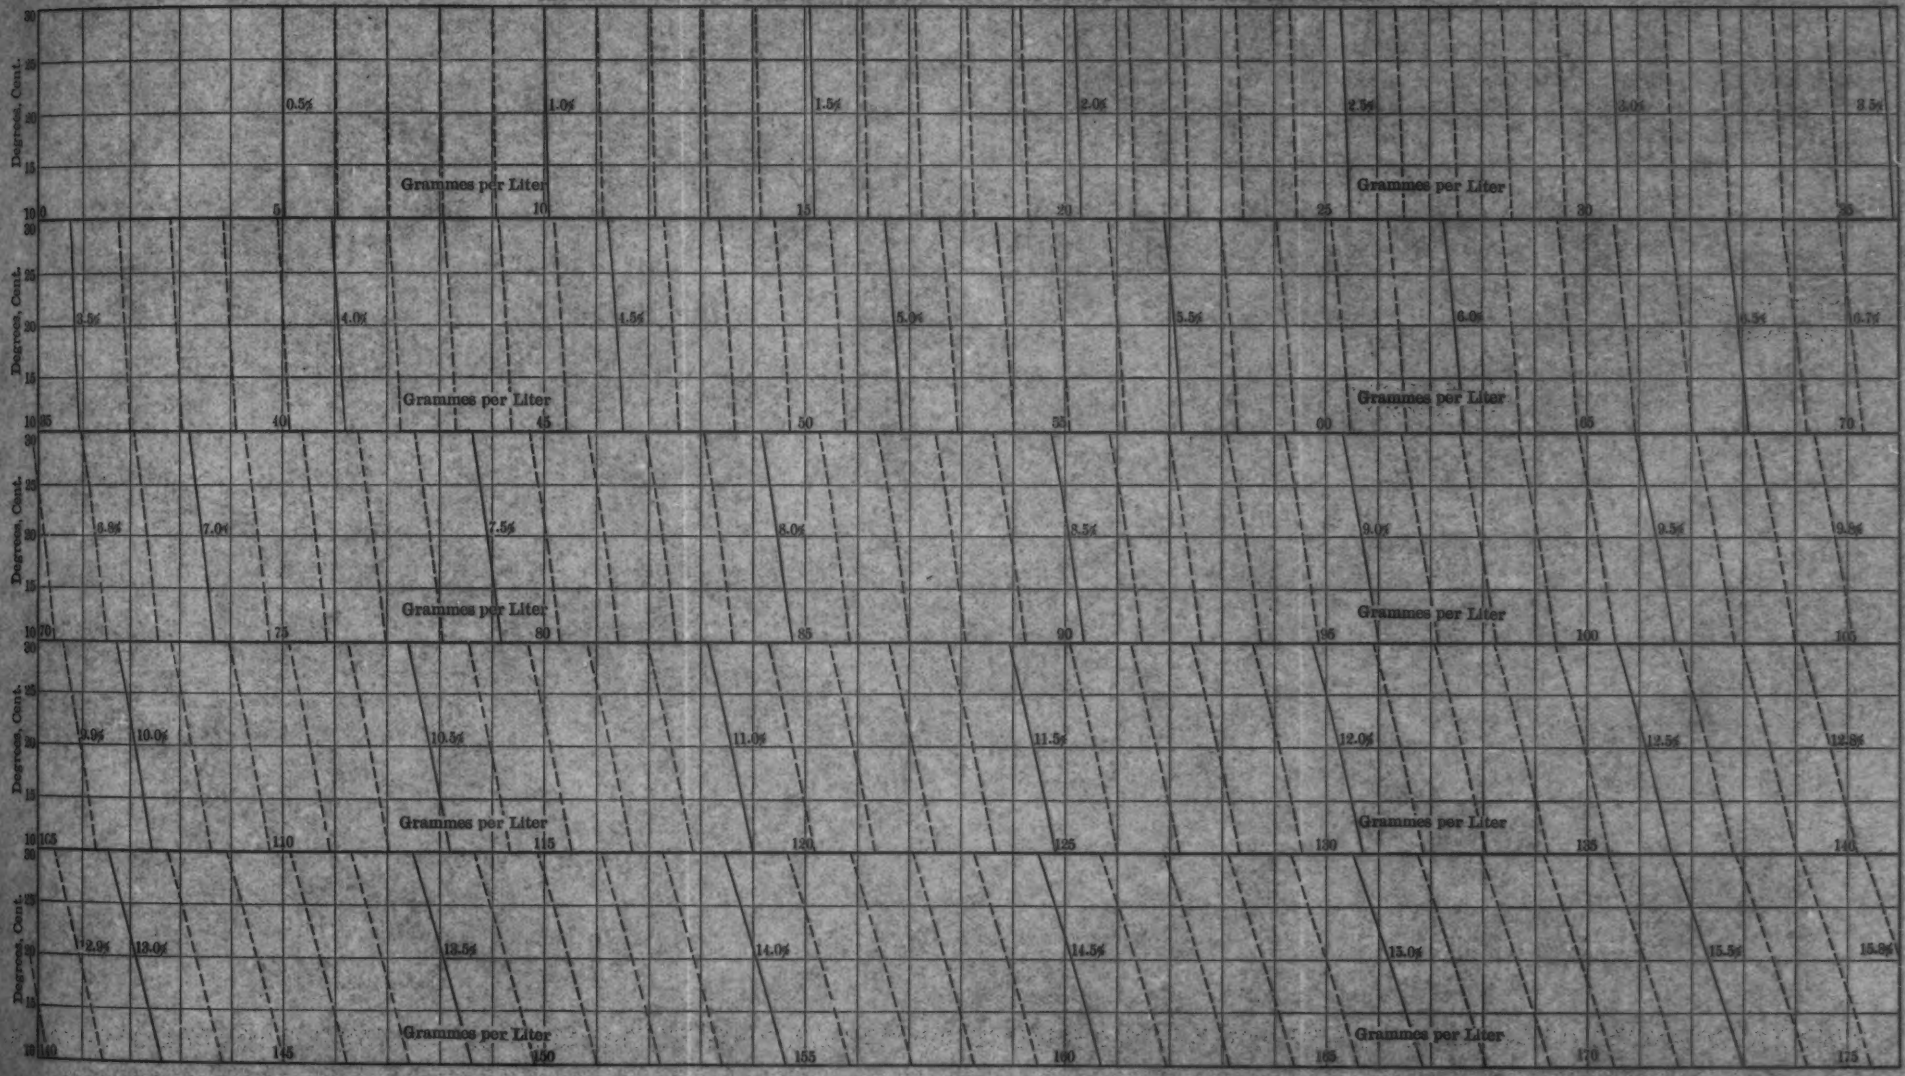
VOL. LXXX, No. 1366.
GROAT ON
CHEMI-HYDROMETRY.

CONCENTRATION AND STRENGTH OF SALT SOLUTIONS BETWEEN 10° AND 30° CENTIGRADE.



the other. The symbol for this ratio will be F for units of weight, and R for units of volume.

When a solution is referred to as "being of a certain percentage" it is meant that this percentage of the total weight of the solution is anhydrous chemical, or, in the case of salt solutions, simply dry salt.

By "strength of solution" will be meant either the percentage of the solution, or its equivalent, the ratio of the weight of salt in solution to the total weight of the solution. This latter ratio will be indicated by p. The percentage of a solution, therefore, is equal to $100\ p$.

By "concentration of a solution" is meant the weight of the chemical in solution per unit of volume; for example, the number of grammes of salt per liter of solution. The symbol, c, represents the concentration of a solution.

When quantities of solution are measured by weight, W and w will be used to represent these weights, and Q or q will represent volumes.

When quantities of silver nitrate, or other standard solution, are measured from a volumetric burette, in executing a titration, the symbol, t, will denote the volume measured, usually in cubic centimeters.

The quantity of a sample of solution to be titrated will be indicated by V in the case of measurement by volume and by S in the case of measurement by weight. Thus, $t \div V$ and $t \div S$ are volumes of silver nitrate consumed per unit quantity of sample, based on the titration, t.

The titration per unit quantity of sample will be denoted by v, so that equations of the form $v = t \div V$ and $v = t \div S$ will occur.

3.—Volume, Strength, Concentration, and Density of a Mixture of Several Known Salt Solutions.—Let the several known solutions be indicated by consecutive subscripts, as 1, 2, 3. . . .n. Then the weight of the solution, x, is W_x, its strength is p_x, and the weight of the contained salt is $W_x\ p_x$. Therefore,

$$\text{Total weight of a mixture of } n \text{ solutions} = \Sigma\, W_x \quad \ldots\ldots (4)$$

$$\text{Total weight of salt in the } n \text{ solutions} = \Sigma\, W_x\, p_x$$

$$\text{Strength of the mixture of } n \text{ solutions} = p = \frac{\Sigma\, W_x\, p_x}{\Sigma\, W_x} \quad \ldots\ldots (5)$$

The reader will not fail to observe that this formula is the same as that for a weighted average, which, of course, is the same as that for the average arm of several forces, or the "arm of gravity."

From the resulting value of p, it will be easy, with Plate XXXIII, to determine the density, d, of the mixture of the n solutions; and with Plates XXXIII, XXXIV, or XXXV, when great accuracy is required, the concentration, c, may be found.

Or, having found the density from Plate XXXIII, the concentration may be computed, thus:

$$\text{Concentration} = c = pd \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

It will also be seen at a glance that

$$Q = \frac{\Sigma W_x}{d} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

9.—Mixture of Two Solutions.—For the ordinary purposes of chemi-hydrometry, mixtures of two solutions, one of which is strong and the other comparatively weak, are of most interest. By omitting subscripts for the strong solution, using the subscript, 1, for the weaker component solution and 2 for the resultant mixture, the following special cases of Equations (5) and (7) may be written at once:

$$\left.\begin{aligned} p_2 &= \frac{wp + W_1 p_1}{w + W_1} \\ Q_2 &= \frac{w + W_1}{d_2} \end{aligned}\right\} \left\{\begin{array}{l} \text{Simple letters refer to strong salt solution. Subscript, 1, refers to 2d component of mixture. Subscript, 2, refers to resulting mixture.} \end{array}\right\} \ldots\ldots (8)$$

Equations (8) are rigorous, and may be used to determine the volume of a mixture of two solutions, in terms of the weights and strengths of the constituents, d_2 becoming known as soon as p_2 has been determined, as has been explained.

It is sometimes required to find the strength of a resultant solution in terms of the ratio of mixture, or of the ratio of dilution of two solutions, thus:

$$p_2 = \frac{p + f p_1}{1 + f} \qquad f = \frac{W_1}{w} \quad \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

and

$$p_2 = \frac{(p - p_1) + F p_1}{F} \qquad \left\{\begin{array}{l} F = W_2 \div w \\ W_2 = w + W_1 \end{array}\right\} \quad \ldots\ldots\ldots\ldots (10)$$

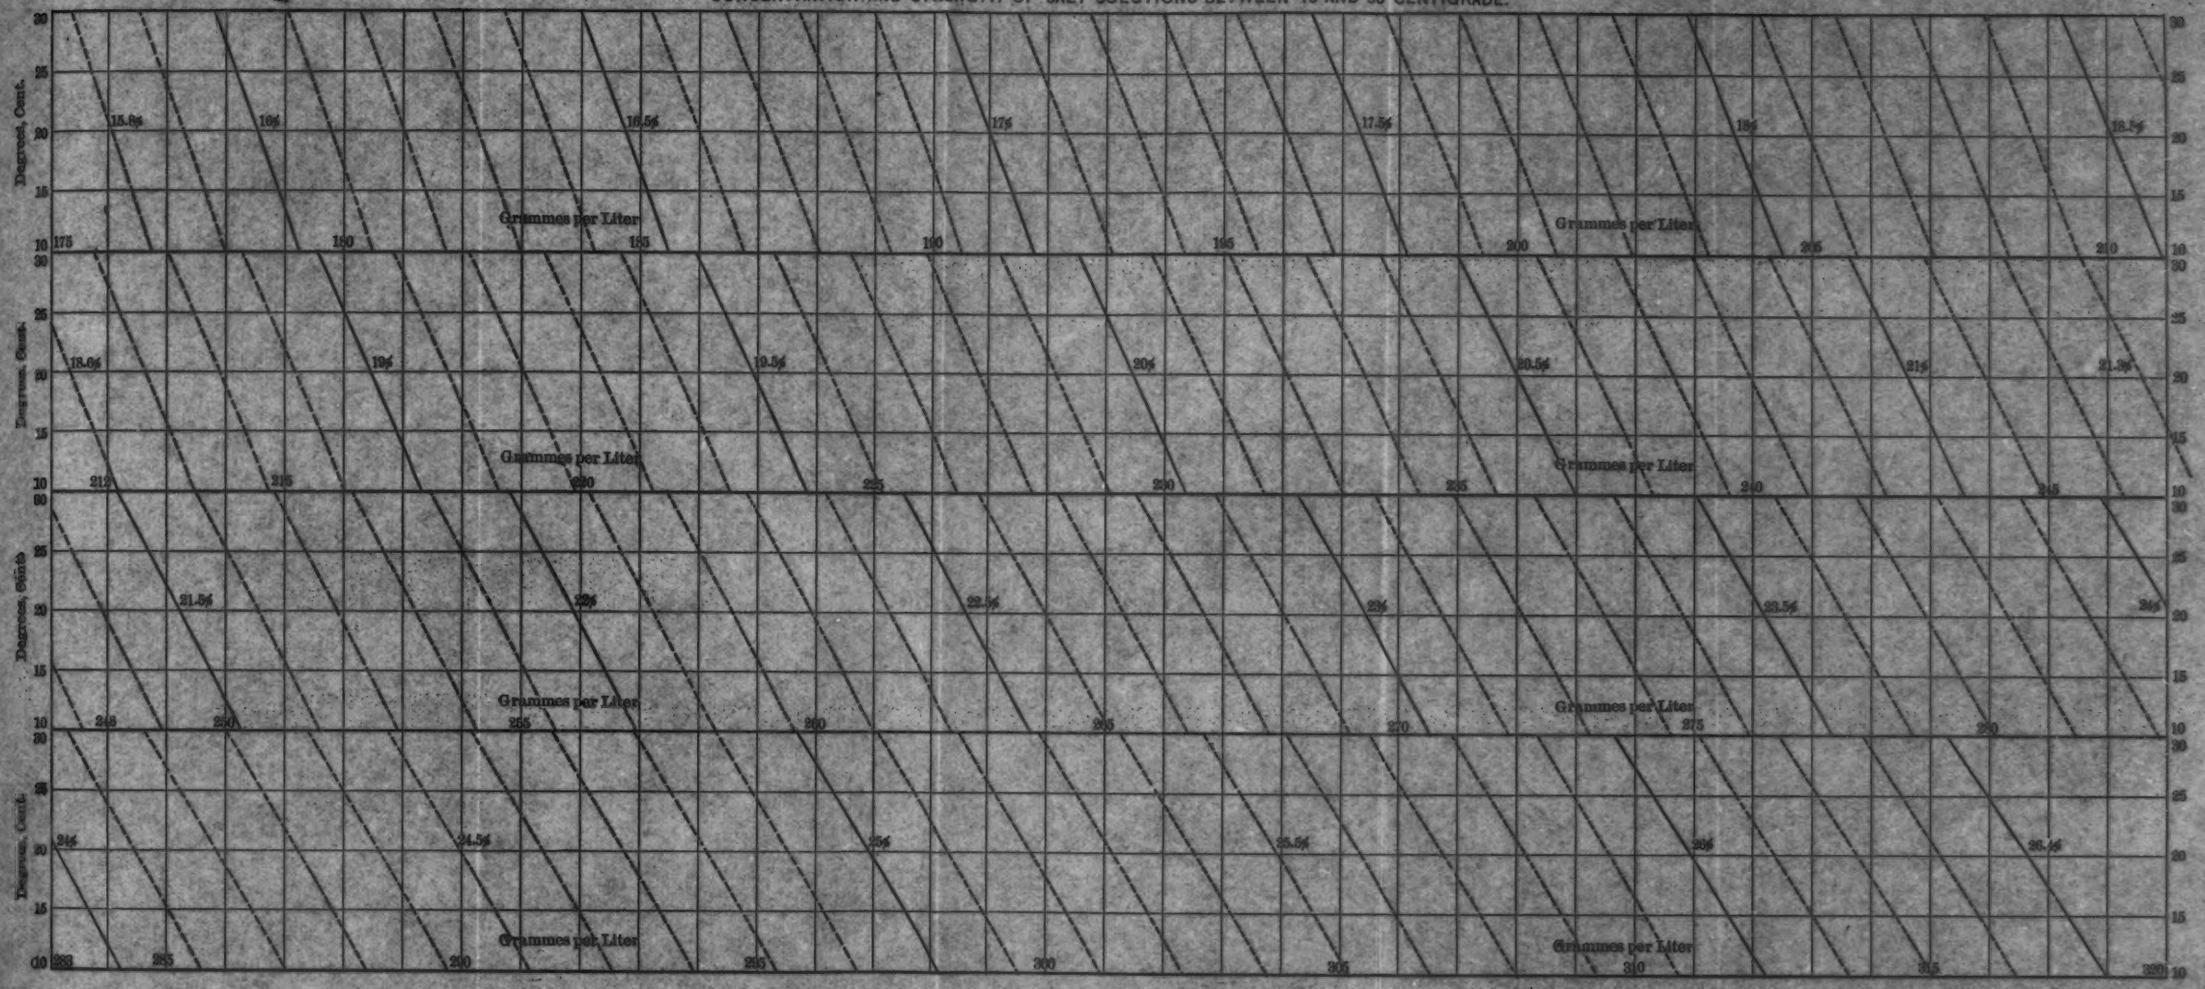
CHEMI-HYDROMETRY.

CONCENTRATION AND STRENGTH OF SALT SOLUTIONS BETWEEN 10° AND 30° CENTIGRADE.



10.—Equations Based on Weights and Strengths Only.—It does not appear that any recognition has been given to the fact that, if the weights of the dosing solution and samples for titration are observed, it will be possible to compute the discharge of a turbine in units of weight, the only units really necessary for a determination of efficiency, without any temperature corrections. The titrations of the samples, of course, are measured in units of volume of silver nitrate, the same as in all cases.

It is very clear, therefore, that much of the labor of computation may be saved by using units of weight in determining quantities of solution and sizes of samples, rather than units of volume. This, however, makes somewhat more trouble in calibrating the chemical tank, as the weight of solution consumed depends on the density, where it is the volume taken from the tank that is measured. On the other hand, this is not so serious a matter as the calculations necessary to ascertain the corrections to be applied to titrations, volumes, and densities.

It follows from this that the ideal method of measuring the dosing solution is by weight, and not by volume. Where this is possible, the method of weights should be adopted unqualifiedly. The importance of this, in the case considered herein, was not realized in time to arrange the testing equipment for the method of weights. However, as the theory for this method is simple, and promises much for the future, it will be given first.

It should be observed, first, that the chemical method determines quantities, that is, weights or volumes of water, or other liquid. Consequently, it is applicable for finding the capacities of tanks and reservoirs, as the volume of such a receiver is equal to the volume of liquid which fills it. Indeed, the capacity of a reservoir, up to any given elevation, can be found immediately by simply ascertaining the quantity of liquid it contains when filled up to that elevation.

This can be done in two ways, one or the other of which may be found the more convenient. The tank may be first filled to the given elevation with the normal water from a water supply, after which an appropriate quantity of salt solution is mixed with the normal water; or, the tank being filled nearly to the given elevation with normal water, salt solution may be added and mixed until the mixture

rises to that elevation. In the first case it is required to find the volume of the normal water before introducing salt, and in the second case it is required to find the volume of the mixture.

In both cases the necessary data are the quantity of salt solution mixed with the normal water and the respective strengths of the salt solution, the normal water, and the mixture. The strengths are determined by chemical analyses, usually by titrations of the samples.

The first of these two cases corresponds to determining the quantity of water passing through a turbine when the salt is injected into the tail-water discharged from the turbine, and samples of the mixture are taken at a point still farther down stream. The second case corresponds to a determination of the quantity of mixture discharged from a turbine when the salt is injected into the head-water, and the mixture is sampled either in the head-race, before it reaches the turbine, or in the tail-race, after passing through the turbine. The difficulties of sampling are discussed in Section 55 *et seq.* See also Sections 58, 59, and 84.

11.—It will facilitate comprehension of the equations to remember that letters without subscripts relate to salt solutions, Subscript 1 relates to normal water, and Subscript 2 relates to the resultant mixture. Thus, w is a quantity of salt solution considered either as a whole, in the case of calibrating a tank, or as a rate of quantity; that is, a quantity per unit of time, as in the case of a turbine test. It may be well, also, to remember that the normal water may contain salt or other chemical initially, thus complicating the equations to a certain extent. Therefore:

Weight of salt in normal water $= W_1 p_1$

" " " " salt solution $= w p$

" " " " resultant mixture $= W_2 p_2$

From which

$$W_1 p_1 + w p = W_2 p_2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

But

$$W_2 = W_1 + w$$

$$W_1 \div w = f$$

$$W_2 \div w = F$$

Therefore,

$$\left.\begin{aligned} f + 1 &= F, \\ f p_1 + p &= F p_2, \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

Thus,
$$\left.\begin{aligned} f &= \frac{F p_2 - p}{p_1} \\ F &= \frac{f p_1 + p}{p_2} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

Again, by eliminating first F, and then f, from Equations (12),

and
$$\left.\begin{aligned} f &= \frac{p - p_2}{p_2 - p_1} \\ F &= \frac{p_1 - p}{p_2 - p_1} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

Equations (14) give the ratio of mixture and the ratio of dilution in terms of the strengths of the three solutions involved. With these ratios may be calculated at once the volumes of the normal head-water and resultant mixture, thus

and
$$\left.\begin{aligned} W_1 &= wf \\ W_2 &= wF \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

Now, if the end points of the titrations are in error by the same relative amount, we should have

$$\left.\begin{aligned} p &= Ev \\ p_1 &= Ev_1 \\ p_2 &= Ev_2 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

as each unit of volume of silver nitrate would correspond to a definite quantity of salt. Consequently, we may write at once, noting that E is a common factor,

and
$$\left.\begin{aligned} W_1 &= w\frac{v - v_2}{v_2 - v_1} \\ W_2 &= w\frac{v - v_1}{v_2 - v_1} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (17)$$

v being the titrations per kilogramme, or other unit of weight, reduced from actual titrations of samples in the laboratory.

It must be carefully observed that this substitution of v for p throughout an equation of chemi-hydrometry is permissible only where the error introduced is either inappreciable or entirely removed by correcting the titrations when seriously affected. The real nature of the errors committed by such substitutions will become more apparent with further study of the subject.

12.—Special Laboratory Procedure and Special Dilutions.—For the present it will suffice to state that the writer eliminates this error by resort to a special laboratory process, the principle involved being as follows:

To have two or more titrations in error by the same amount, and therefore by the same relative amount, the samples must be of exactly the same size and just alike in all respects; the standard solution and the indicator must each have the same strength in the two or more cases; and, in fact, the samples and titrations in the several cases must be just alike in all other respects as regards the conditions under which the operations take place.

The truth of this proposition, being axiomatic, needs no comment. The application of the principle is effected by making a special dilution in the laboratory which is to have the same ratios of mixture and dilution as has the mixture of salt solution and normal feed-water in the actual test. Of course, the same salt solution and normal feed-water must be used in the laboratory as on the test.

This procedure cannot be accomplished without advance knowledge of the actual ratio of dilution. In any case, it will always be possible to have a more or less approximate value for this ratio, and the approximate value may be used in making up preliminary special dilutions, from which a close approximation to the true ratio may be computed by the methods immediately to follow, thus leading to a second approximation, which, in most cases, will be sufficiently exact. In fact, it will be found in most actual tests that the true value of the ratio will be known in advance with sufficient closeness to enable the making of satisfactory special dilutions.

It will seldom chance to be the case, however, that the ratios of mixture and dilution actually used in the laboratory will prove to be equal to the true ratios corresponding. It is necessary, therefore, to distinguish carefully between the actual ratios, samples, and titrations and the special ratios, samples, and titrations of the laboratory dilutions. A prime, therefore, will be affixed to the letters and symbols pertaining to the special dilutions; thus, r', R', and w' are, respectively, the ratio of mixture, ratio of dilution, and weight of salt solution used in making up a special dilution.

13.—Assume, then, that a test has actually been made, that samples of percentages, p and p_2, have been taken, and that w has been

measured. Further, that special dilutions have been prepared, and that the quantities, f', F', w', p', and p_2', have also been observed. There may then be written, from Equations 14, Section 11, the following relations:

$$\left.\begin{aligned} \frac{F}{f} &= \frac{p - p_1}{p - p_2}, \text{ for the actual test,} \\ \text{and} \quad \frac{f'}{F'} &= \frac{p - p_2'}{p - p_1}, \text{ for the special dilutions.} \end{aligned}\right\} \quad \ldots\ldots\ldots (18)$$

It may be helpful here to remark that p and p_1 are the same in both preceding equations, as the same salt solution and the same normal feed-water have been used in the laboratory and on the actual test. Further, the unknown, p_1, may now be eliminated from Equations (18), thus:

$$\frac{Ff'}{fF'} = \frac{p - p_2'}{p - p_2} = 1 + \frac{p_2 - p_2'}{p - p_2} \quad \ldots\ldots\ldots (19)$$

Now put

$$\left.\begin{aligned} x &= \frac{p_2 - p_2'}{p - p_2} \\ \text{and} \quad y &= \frac{p_2 - p_2'}{p - p_2'} \end{aligned}\right\} \quad \ldots\ldots\ldots (20)$$

from which

$$\frac{x}{y} = \frac{1}{1 - y} = 1 + x \quad \ldots\ldots\ldots (21)$$

Therefore,

$$\frac{Ff'}{fF'} = 1 + x, \text{ or}$$

$$1 + \frac{1}{f} = \left(1 + \frac{1}{f'}\right)(1 + x) = 1 + \frac{1}{f'} + \frac{F'x}{f'} \quad \ldots\ldots\ldots (22)$$

as $F = f + 1$, and $F' = f' + 1$, by Equations (12), Section 11.

From Equation (22) may be written at once

$$f = \frac{f'}{1 + F'x}, \text{ and } \left(x = \frac{p_2 - p_2'}{p - p_2}\right) \quad \ldots\ldots\ldots (23)$$

Again,

$$\frac{fF'}{Ff'} = \frac{1}{1 + x} = 1 - y \quad \ldots\ldots\ldots (24)$$

or

$$1 - \frac{1}{F} = \left(1 - \frac{1}{F'}\right)(1 - y) \quad \ldots\ldots\ldots (25)$$

which by analogy gives at once

$$F = \frac{F'}{1 + f'y}, \text{ and } \left(y = \frac{p_2 - p_2'}{p - p_2'}\right) \quad \ldots\ldots\ldots (26)$$

If it is required to have equations in terms of either the rate of mixture or rate of dilution, they may be written out as follows, by simply putting $F - 1$ for f, or $f + 1$ for F, thus:

Method of special dilutions. Equations based on weights of samples.

$$\left.\begin{aligned} f &= \frac{f'}{1 + (f' + 1)\,x} \\ f &= \frac{F' - 1}{1 + F'\,x} \\ F &= \frac{f' + 1}{1 + f'\,y} \\ F &= \frac{F'}{1 + (F' - 1)\,y} \end{aligned}\right\} \left\{\begin{aligned} \left(x = \frac{p_2 - p_2'}{p - p_2}\right) \\ \left(y = \frac{p_2 - p_2'}{p - p_2'}\right) \end{aligned}\right\} \quad (27)$$

14.—It will not always be advisable to eliminate p_1 in this manner. Frequently, it will be advisable to determine p_1 by Equations (14), from the known ratio of mixture, or ratio of dilution, used in the preparation of the special dilutions, and then determine F, or f, by a second application of Equations (14), with the resulting value of p_1 introduced.

An advantage secured by this procedure arises when the normal feed-water for the turbine runs constant in salt content. In this case the value of p_1, reduced to standard conditions, should be the same in all the tests, if care has been taken to keep the silver nitrate at the same standard strength. An error in the laboratory process is then made apparent by a discrepancy among the corrected values of p_1.

The laboratory procedure is exactly the same as before, the only difference being in the method of calculation, which is sufficiently indicated by the following equations, derived from Equations (13) or (14).

By the method of "Special Dilutions."

$$\left.\begin{aligned} p_1 &= \frac{F'\,p_2' - p}{f'} \quad \text{(a check on uniformity of normal head-water)} \\ f &= \frac{p - p_2}{p_2 - p_1} \\ \text{or, } F &= \frac{p - p_1}{p_2 - p_1} \end{aligned}\right\} \quad \ldots(28)$$

15.—Object of the Special Dilutions.—The influence of the special dilutions toward eliminating the errors of titration may now be more fully explained.

An inspection of Equations (14), Section 11, will show at a glance that, if all the strengths of the solutions as determined by the titrations are in error by the same relative amount, the ratios of mixture and dilution, and therefore the quantities of liquid to be measured, will, nevertheless, be correctly determined by the formulas.

If the percentages, p, p_1, p_2, however, are not in error by the same relative discrepancy, then an error of greater or less moment will be introduced in the calculations, and, as a consequence, they are based on fallacious data. It should be observed here that p is relatively much larger than p_2 and p_1, and that p_2 may be any number of times larger than p_1. Thus, in the case of the tests to be discussed, the salt solution used was near the saturation point, but the normal canal water carried only about 15 mg. of salt per liter. The quantity of salt injected into the head-water was from 3 to 4 times as much as the water contained initially.

The corresponding values of v, v_2, and v_1, therefore, were about 540 000, 110, and 25 c.c. per liter of the respective solutions, when the silver nitrate was of a concentration of about 1.56 grammes per liter of distilled water. The respective values of 100 p, 100 p_2 and 100 p_1, therefore, were about 24.5%, 0.00592%, and 0.00134%, and c, c_2, and c_1, were about 290, 0.0591, and 0.0134 grammes per liter of the corresponding sample.

Table 2 facilitates a comparison of these figures.

TABLE 2.—COMPARISON OF SALT AND SILVER NITRATE EQUIVALENTS, AND STRENGTHS AND DENSITIES OF SALT SOLUTION, HEAD-WATER, AND TAIL-WATER SAMPLES INVOLVED IN THE TESTS.

$AgNO_3$ solution contains about 1.56 grammes per liter of distilled water.

Quantities compared.	Salt solution.	Tail-water.	Head-water.
Cubic centimeters of silver nitrate per liter of sample	540 000	110	25
Ditto per kilogramme of sample	456 200	110.2	25
Percentage strength of solution (100p)	24.50	0.00592	0.001342
Densities	1.1537	0.9984	0.9984
Concentration, in grammes per liter	290	0.0591	0.0134

Thus, by Equations (14), Section 11, the ratio of dilution by weight will be:

$$F = \frac{24.50 - 0.00134}{0.00592 - 0.00134} = \frac{24.50}{0.00458} = 5\,349.3 \ldots\ldots (29)$$

or, for every pound of salt solution injected into the head-race there were, as an average, 5 349 lb. of mixture flowing through the turbine.

Now the percentages, $100\ p_1 = 0.00134$, and $100\ p_2 = 0.00592$, are both in error relative to $100\ p = 24.50$, as the titrations were not of samples which were alike in all respects. For example, the titration for p is made by first diluting 10 c.c.* of salt solution to 1 liter and then placing 10 c.c. of this dilution in a casserole for the actual titration, which, therefore, would be about 54 c.c. of silver nitrate, the ten-thousandth part of what it would be for a whole liter of salt solution. On the other hand, the titrations of the normal head-water and of the tail-water are made by evaporating 500 c.c. of sample to about 10 c.c. in a casserole before making the titrations. Thus, these samples have been reduced by evaporation, whereas the salt solution sample has been increased in size by diluting with distilled water. Moreover, the concentration of the tail-water sample, and consequently its titration, are each about 4½ times what they are for the normal head-water, thus rendering p_2 and p_1 relatively inconsistent with each other as well as with p.

Under the conditions cited, it can be shown that the titration of normal head-water should be decreased about 0.14 c.c. for each ½-liter sample, a little more than 1%; and the titration of the tail-water, the ½ liter evaporation titrating so nearly equal to the titration of the salt solution, namely, about 55 c.c., needs scarcely any correction. Therefore, a more correct value for the ratio of dilution will be

$$F = \frac{24.5}{0.00592 - 0.001325} = 5\ 332 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

which is seen to differ from the uncorrected ratio by about ⅓ of 1%, which, relatively, was too large an error to pass without notice in the turbine tests. The object of the special dilutions is to eliminate this error without the necessity for determining the corrections to be applied to the titrations.

16.—Function of the Special Dilutions.—The operation of the special dilutions to eliminate the errors of titration may be illustrated by an application of any of Equations (27) to the problem of the preceding paragraph.

* The method of weights was not used in the tests in question. Hence volumes instead of weights are given here.

First, let it be observed that the errors of titration can affect only x and y of the equations, because the results of the titrations enter only these quantities, and f' or F' are determined independently by the relative weights of the samples. Consequently, the effect of an error can be discovered by ascertaining the effect on x, or y, and then introducing the erroneous value of x, or y, in the corresponding equation.

Let S, S_2, and S'_2 be the weights of the samples at the times they are actually titrated. Let ρ_2, and ρ'_2 be the ratios of evaporation of the tail-water and special dilutions, that is, the ratio of the measured weight of a sample to its weight when ready for titration after the evaporation. In order to have the titrations as nearly alike as possible, the dilution of the salt solution and evaporations of the tail-water and special dilutions must be proportioned so that the actual samples titrated will be as nearly alike as possible. This will mean that the actual weights titrated and the strengths of these samples must be the same, and, therefore, their volumes must be the same. Thus, if ρ is the ratio of dilution of the salt solution with distilled water, c_s the concentration of the silver nitrate, and e the actual equivalent weight of salt per unit weight of silver nitrate consumed in titration, we must have,

$$\left.\begin{aligned} p = v\, c_s\, e &= \rho \frac{t}{S} c_s\, e \\ p_2 = v_2\, c_s\, e_2 &= \frac{t_2}{\rho_2 S_2} c_s\, e_2 \\ p_2' = v_2'\, c_s\, e_2' &= \frac{t_2'}{\rho_2' S_2'} c_s\, e_2' \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (31)$$

If the laboratory procedure is properly arranged, R' will be the same as R, so that the titrations for t_2 and t'_2 will be exactly alike, and, therefore, $t_2 = t'_2$, $\rho_2 = \rho'_2$, $S_2 = S'_2$, and $e_2 = e'_2$, but e will not necessarily be equal to either e_2 or e'_2, owing to the dilution of the salt solution with distilled water instead of normal head-water, and to other obvious differences among the conditions under which the operations on the salt solution and the other two kinds of samples take place.

However, we may write

$$\left.\begin{aligned} S &= S_2 = S_2' \\ e_2 &= e_2' \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (32)$$

and $\rho_2 = \rho_2'$

With Equations (31) and (32) we may substitute in the values of x and y to obtain

$$\left.\begin{aligned} x &= \frac{p_2 - p_2'}{p - p_2} = \frac{v_2 - v_2'}{v - v_2} = \frac{t_2 - t_2'}{T - t_2} \\ y &= \frac{p_2 - p_2'}{p - p_2'} = \frac{v_2 - v_2'}{v - v_2'} = \frac{t_2 - t_2'}{T - t_2'} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (33)$$

where

$$T = \rho\, \rho_2 \frac{e}{e_2} t$$

which shows that, when $t_2 = t'_2$, the samples having been made exactly alike, $x = 0$ and $y = 0$, whether there is any error in t, that is, in T, or the contrary. It is clear, therefore, that:

When the ratio of dilution for the special dilutions is the same as that in the actual test, Equations (27) are rigidly correct and independent of any error in the titration of the salt solution.

We may go further, and say:

When the difference between t_2 and t'_2 is sufficiently small, the error in t will have no appreciable effect on the values of the ratios computed by Equations (27), and it is also apparent that any errors due to the inequality of t_2 and t'_2 will be negligible under similar conditions.

Now, to apply Equations (27) to the problem of Section 15, we must suppose a special dilution made up by taking, say, 10 grammes of salt solution, diluting this to 1 000 grammes with normal head-water and then diluting 10 grammes of the resultant dilution to, say, 600 grammes, so as to produce a dilution of 1 to 6 000, or $R' = 6\,000$. Breaking up a dilution in this way keeps down the size of the quantities treated in the laboratory.*

Under this treatment, a sample of 500 grammes of the dilution would, after evaporation to about 10 grammes, titrate to 50.335 c.c. of silver nitrate. This evaporation to 10 grammes requires that the sample of dilute salt solution should also be of 10 grammes weight, though a dilution of 10 grammes to 1 kg. would cause the titration to be one ten-thousandth of the titration for 1 kg., as shown in Table 2, Section 15, which is 45.62 c.c., or $t = 45.62$. All this

* In making successive dilutions, however, it is always better to make the partial dilutions equal, wherever practicable, this being on the side of economy and accuracy. Thus, if the two flasks had equal capacities of 750 c.c., the ratio would have been $75^2 = 5\,625$, instead of 6 000. The latter ratio is used merely for the purpose of a particular illustration.

requires that $\rho = 100$ and $\rho_2 = 50$, so that $\rho\,\rho_2 = 5\,000$. If we neglect the error in $e_1 \div e_2$, calling this ratio unity, we may write

$$T = \rho\,\rho_2\,t\,\frac{e}{e_2} = 5\,000 \times 45.62 = 228\,100 \ldots\ldots\ldots\ldots (34)$$

Simultaneously with the evaporations of the special dilution, there would be evaporated a number of tail-water samples which, in accord with the problem of Section 15, titrate to 55.10 c.c. of silver nitrate, or $t_2 = 55.10$.

The value of y then becomes

$$y = \frac{55.10 - 50.335}{228\,100 - 50.335} = 0.00002089 \ldots\ldots\ldots\ldots (35)$$

Now, it can be shown that the errors due to titration, under the circumstances of the problem, would not exceed 0.01 c.c. in the titration of t'_2, and not more than 0.03 c.c. in the titration of t, in order to leave the same relative error in all three titrations. See Section 43.

Indeed, these assumed errors are certainly large rather than small, as will appear in the study of errors, Section 42 *et seq.* Hence, affecting the titrations, t, t'_2, with these errors, which are to be subtracted in both cases, we shall have for the new value of y, observing that now $e \div e_2$ is properly made equal to unity,

$$\text{corrected } y = \frac{55.10 - 50.325}{227\,950 - 50.0} = 0.00002095 \ldots\ldots\ldots\ldots (36)$$

By the last of Equations (27) the ratio of dilution in the tail-race will be, for Equations (35) and (36), respectively,

$$\left.\begin{aligned} F_{35} &= \frac{6\,000}{1 + 5\,999\,y_{35}} = 5\,332 \\ F_{36} &= \frac{6\,000}{1 + 5\,999\,y_{36}} = 5\,330 \end{aligned}\right\} \ldots\ldots\ldots\ldots (37)$$

Thus, by neglecting the errors of titration, when $t = 45.62$, $t_2 = 55.10$, $t'_2 = 50.325$, the method of special dilutions gives the discharge correct to 2 in 5 332, or with an error of less than 0.04%, because, by applying the corrections as in Equation (36), the true ratio of dilution is seen to be 5 330.

Now, in all actual cases, t, t_2, and t'_2 can, without much trouble, be brought into much closer agreement than has been here supposed, and by a second treatment they may even be made equal if desired. Hence, it is clear that the laboratory work can be made to yield results which

are precise to one or two hundredths of 1%, in so far as systematic errors are concerned. As to accidental errors, there is no difficulty in checking the means of two sets of six or eight titrations to within 0.04 or 0.05%, so that a precision of $\frac{1}{10}$ of 1% is not difficult to realize.

If Equation (30) and the last of Equations (37) were actual cases, instead of mere illustrative problems, it would be wise to consider the latter as the more exact, or as having the greater weight, because errors in t, that is, in the numerator of Equation (30) and in the denominators of x and y, have much less effect on Equations (27) than on Equations (14).

Although the problems of this and the preceding section have been given as merely illustrative, the suppositions are based on the figures of Tables 2, 4, 5, and 6, which are derived from the results of actual tests. The errors thus computed, therefore, are very close estimates of any actual errors that would occur under similar circumstances.

17.—Ratio of Evaporation Nominal Only.—The ratio of evaporation has been defined and introduced into Equations (31) and (33). It should be observed that this is merely a nominal ratio of evaporation, as the evaporation is not a measured quantity. Its real significance in the equations may be better understood as being the ratio of the weight of a sample, as measured for evaporation, to the weight of a sample of dilute salt solution, as measured for titration. Thus, S is the weight of a dilute salt solution sample, say 10 grammes, and $\rho_2 S_2$ is the true weight of a tail-water sample, about 500 grammes, S_2 being equal to S for samples of equal volume. Thus $\rho_2 = 50$ in that case.

The evaporations will be closely enough equal if they are all made as nearly equal to the volume of a dilute salt solution sample as the eye can estimate by actual comparison when both samples are in exactly equal casseroles. A dilute salt solution sample can be used as a "check" for the purpose of this comparison.

18.—Volumetric Equations Involving Densities and Strengths.—Equations (27) contemplate the measurement of samples by weight, and determine the weight of water passing through the turbine during a test. It is more common in chemistry to measure quantities of liquid samples by volume. This will add somewhat to the complexity of the

equations, as has been explained. However, the equations will prove convenient for many purposes, and are therefore set forth, as follows:

According to the definitions, Section 7, we must have

$$\left.\begin{aligned} f &= \frac{W_1}{w} = \frac{Q_1 d_1}{q d} = r \frac{d_1}{d} \\ F &= \frac{W_2}{w} = \frac{Q_2 d_2}{q d} = R \frac{d_2}{d} \\ f' &= \frac{W'_1}{w'} = \frac{Q'_1 d_1}{q' d} = r' \frac{d_1}{d} \\ F' &= \frac{W'_2}{w'} = \frac{Q'_2 d'_2}{q' d} = R' \frac{d'_2}{d} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (38)$$

Hence, in order to introduce volumes and densities in Equations (27), Section 14,* it will be necessary merely to substitute these values of the weight ratios in the proper places and thus obtain

$$\left.\begin{aligned} r &= \frac{r'}{1 + \left(r' \frac{d_1}{d} + 1\right) x} \qquad x = \frac{p_2 - p'_2}{p - p_2} \\ r &= \frac{R' \frac{d'_2}{d_1} - \frac{d}{d_1}}{1 + R' \frac{d'_2}{d} x} \\ R &= \frac{\left(r' \frac{d_1}{d} + 1\right)}{1 + r' \frac{d_1}{d} y} \qquad y = \frac{p_2 - p'_2}{p - p'_2} \\ R\dagger &= \frac{R' \frac{d'_2}{d_2}}{1 + \left(R' \frac{d'_2}{d} - 1\right) y} \end{aligned}\right\} \quad \ldots (39)$$

By the method of special dilutions, the equations involving densities and strengths.

19.—Volumetric Equations Involving Concentrations and Strengths.—These equations may be deduced by substituting $c \div p$ for d, etc., in Equations (39), but the following method is easier and serves better

* These substitutions may be made in other equations. For example, in Equations (14), Section 11, to obtain equations involving r and R.

† It is remarked that this last equation is really the only one which is entirely free from the properties of the normal head-water. Also notice that concentrations, densities, and percentages are connected by Table 1, Equations 2, 3, 4, and Plates XXXIII, XXXIV, and XXXV, so that, any one being given, the other two may be found. Thus these equations express the volumetric ratios in terms of either density or percentage when taken in conjunction with the tables, equations, or diagrams.

to familiarize one with the relations existing among the quantities involved. It is first to be remembered that Equations (39) were established by the use of Equations (14), Section 11, Equations (20-21), Section 13, Equations (27), Section 14, and Equations (38), Section 18. Further, let

W_{s1} = the total weight of salt in the head-water;
W_{s2} = " " " " " " " " tail-water;
w_s = " " " " " " " " salt solution;
$f_s = W_{s1} \div w_s$;
$F_s = W_{s2} \div w_s$;
P = ratio of total weight of salt solution to weight of salt content;
P_1 = ratio of total weight of head-water to weight of salt content;
P_2 = ratio of total weight of tail-water to weight of salt content.

Thus
$$P = 1 \div p, \text{ etc.}$$

Then
$$\left.\begin{aligned} W_{s1} P_1 + w_s P &= W_{s2} P_2 \\ W_{s1} + w_s &= W_{s2} \\ \text{or} \quad f_s P_1 + P &= F_s P_2 \\ \text{and} \quad f_s + 1 &= F_s \end{aligned}\right\}$$

from which
$$\left.\begin{aligned} f_s &= \frac{P - P_2}{P_2 - P_1} \\ F_s &= \frac{P - P_1}{P_2 - P_1} \end{aligned}\right\} \text{(See Equations (14))} \quad \ldots\ldots\ldots\ldots (40)$$

Hence, if we put
$$\left.\begin{aligned} X &= \frac{P_2 - P'_2}{P - P_2} \\ Y &= \frac{P_2 - P'_2}{P - P'_2} \end{aligned}\right\} \text{(See Equations (20))} \quad \ldots\ldots\ldots (41)$$

and, similar to Equations (38),
$$\left.\begin{aligned} f_s &= \frac{W_{s1}}{w_s} = \frac{Q_1 c_1}{q c} = r \frac{c_1}{c} \\ F_s &= \frac{W_{s2}}{w} = \frac{Q_2 c_2}{q c} = R \frac{c_2}{c} \end{aligned}\right\} \text{(See Equations (38))} \quad \ldots\ldots (42)$$

We are, by analogy, able to write out at once, from a mere inspection of Equations (27),

$$f_s = \frac{f'_s}{1 + (f'_s + 1)\,X}$$

$$f_s = \frac{F'_s - 1}{1 + F'_s\,X}$$

$$F_s = \frac{f'_s + 1}{1 + f'_s\,Y}$$

$$F_s = \frac{F'_s}{1 + (F'_s - 1)\,Y}$$

(See Equations (27)) ..... (43)

By further analogy, from Equations (39), substituting c for d, etc.,

$$r = \frac{r'}{1 + \left(r'\frac{c_1}{c} + 1\right)\frac{p}{p'_2}\,x}$$

$$r = \frac{R'\frac{c'_2}{c_1} - \frac{c}{c_1}}{1 + R'\frac{c'_2}{c}\,\frac{p}{p'_2}\,x}$$

$$R = \frac{r'\frac{c_1}{c} + 1}{1 + r'\frac{c_1}{c}\,\frac{p}{p_2}\,y}$$

$$R = \frac{R'\frac{c'_2}{c_2}}{1 + \left(R'\frac{c'_2}{c} - 1\right)\frac{p}{p_2}\,y}$$

$X = \frac{p}{p'_2}\,x$

$Y = \frac{p}{p_2}\,y$

By the method of special dilutions, the equations involving concentrations and strengths.

(See Equations (39)) ..... (44)

20.—It must not be overlooked that in some cases it may be of more advantage to compute the strength, or other property, of the normal head-water, from the special dilutions than to eliminate it entirely from the equations. Thus, for example, by substituting in Equations (28) from Equations (38), there may be obtained

$$p_1 = \frac{R'\frac{d'_2}{d}\,p'_2 - p}{r'\frac{d_1}{d}}$$

or

$$p_1 = \frac{R'\frac{d'_2}{d}\,p'_2 - p}{R'\frac{d'_2}{d} - 1}$$

(See Equations (28)) By the method of special dilutions, values of p_1 to check constancy of salt content in head-water. ..... (45)

$$r = \frac{d}{d_1}\,\frac{p - p_2}{p_2 - p_1} \qquad \left.\begin{aligned} f &= r\frac{d_1}{d} \\ F &= R\frac{d_2}{d} \end{aligned}\right\} \qquad (46)$$

$$R = \frac{d}{d_2}\,\frac{p - p_1}{p_2 - p_1}$$

which, by giving the value of p_1, d_1, etc., may serve as a check on the constancy of head-water concentration, density, etc.

Observe that the first of Equations (46) may be used to find the volume of a quantity of solution with which a known volume of standard solution has been mixed, and the second equation gives the volume resulting from the mixture of two solutions when the strengths and densities of all the solutions and the volume of one of them are known, thus

$$\left.\begin{aligned} Q_1 &= rq \\ Q_2 &= Rq \end{aligned}\right\} \qquad (47)$$

21.—Similarity of Relations Involving Density, Strength, and Concentration.—In view of the definitions, there may be written, along with Equation (11),

$$\left.\begin{aligned} W_1 p_1 + w p &= W_2 p_2 \\ Q_1 d_1 + q d &= Q_2 d_2 \\ Q_1 c_1 + q c &= Q_2 c_2 \end{aligned}\right\} \qquad (48)$$

By dividing by w or q, there results

$$\left.\begin{aligned} f p_1 + p &= F p_2 \\ r d_1 + d &= R d_2 \\ r c_1 + c &= R c_2 \end{aligned}\right\} \qquad (49)$$

By a further division by p, d, or c, using the following notation

$$\left.\begin{aligned} P_x &= \frac{p_x}{p} \\ D_x &= \frac{d_x}{d} \\ C_x &= \frac{c_x}{c} \end{aligned}\right\} \qquad (50)$$

there results

$$\left.\begin{aligned} fP_1 + 1 &= FP_2 \\ rD_1 + 1 &= RD_2 \\ rC_1 + 1 &= RC_2 \end{aligned}\right\} \qquad (51)$$

Moreover, from Equation (6),

$$C = PD, \text{ etc.} \qquad (52)$$

To these should be added the analogous forms, Equations (40), and the other relations of Section 19. The similarity is apparent, and will be of frequent service in deriving other relations.

22.—Volumetric Equations Involving Densities and Concentrations.—The first two of these equations may be derived most simply by solving the last pair of Equations (51) for r and R, respectively.

Hence,

$$\left.\begin{aligned} r &= \frac{D_2 - C_2}{D_1 C_2 - D_2 C_1} \\ R &= \frac{D_1 - C_1}{D_1 C_2 - D_2 C_1} \end{aligned}\right\} \qquad (53)$$

Of course, to solve for quantities, we must use

$$\left.\begin{aligned} Q_1 &= qr \\ Q_2 &= qR \end{aligned}\right\} \qquad (54)$$

These equations are subject to the objection that the titration for c_i will be more or less erroneous, as set forth fully in Sections 15 and 16. Hence C_i and D_i, also, are likely to be in error by an amount larger than the permissible margin. This source of error may be removed by resort to special dilutions, also discussed in the two sections mentioned. An independent solution could be made by forming, from Equations (53), two equations corresponding to Equations (18), Section 13, after which the solution would proceed in a manner quite similar to that given in the remainder of Section 13; but the solution may be made more expeditiously by simply substituting in Equations (39), as follows:

$$\left.\begin{aligned} x &= \frac{p_2 - p'_2}{p - p_2} = \frac{\frac{c_2}{d_2} - \frac{c'_2}{d'_2}}{\frac{c}{d} - \frac{c_2}{d_2}} = \frac{C_2 D'_2 - C'_2 D_2}{D_2 - C_2} \frac{1}{D'_2} \\ y &= \frac{p_2 - p'_2}{p - p'_2} = \frac{\frac{c_2}{d_2} - \frac{c'_2}{d'_2}}{\frac{c}{d} - \frac{c'_2}{d'_2}} = \frac{C_2 D'_2 - C'_2 D_2}{D'_2 - C'_2} \frac{1}{D_2} \end{aligned}\right\} \qquad (55)$$

Thus, with the aid of the second of Equations (51), noting that $d_1 \div d = D_1$, etc.,

$$\left.\begin{aligned} r &= \frac{r'}{1 + (r' D_1 + 1) x} \\ r &= \frac{R' \frac{D'_2}{D_1} - \frac{1}{D_1}}{1 + R' D'_2 x} \\ R &= \frac{r' D_1 + 1}{1 + r' D_1 y} \\ R &= \frac{R' \frac{D'_2}{D_2}}{1 + (R' D'_2 - 1) y} \end{aligned}\right\} \quad \left\{\begin{array}{l} \text{By the method of special} \\ \text{dilutions, the equations} \\ \text{involving densities and} \\ \text{concentrations. See} \\ \text{Equations (55).} \end{array}\right\} \quad \ldots (56)$$

the last equation being the only one of the set free of D_1 as well as C_1.

The values for x and y are here supposed to be the last of those given in Equations (55), thus Equations (56) will be expressed entirely in terms of densities and concentrations. Of course, the reader will understand that the densities should be known, in fact, rather than be computed from the relations given in Table 1, Plates XXXIII, XXXIV, or XXXV, or Equations (4), which are supposed to apply only to solutions of pure sodium chloride in distilled water rather than to solutions of commercial salt in river water. However, in many cases, results will be sufficiently exact under the latter circumstances, where there is not much foreign matter carried in the water.

In case it is desired to check the salt content of the normal head-water from day to day, or test to test, as in Equations (28), we may, from the special dilutions, determine the value of C_1 in Equations (53) and then determine r or R by the same equations, but making use of the titrations of the tail-water instead of those of the special dilutions, just as in Equations (28); thus, from Equations (53),

$$\left.\begin{aligned} \frac{D_2 - C_2}{r} &= \frac{D_1 - C_1}{R} \\ \text{or} \qquad C_1 &= \frac{r D_1 - R D_2 + R C_2}{r} \\ &= \frac{R C_2 - 1}{r}, \end{aligned}\right\} \quad \ldots (57)$$

since $rD_1 - RD_2 = -1$, *by* Equations (51).

Hence, with special dilutions,

$$C_1 = \frac{R'\,C'_2 - 1}{r'}$$

$$r' = \frac{D'_2 - C'_2}{D_1\,C'_2 - D'_2\,C_1}$$

$$r = \frac{D_2 - C_2}{D_1\,C_2 - D_2\,C_1}$$

or $$R = \frac{D_1 - C_1}{D_1\,C_2 - D_2\,C_1}$$

(Equations involving densities and concentrations. Values of C_1 to check constancy of salt content.) ...(57)

These equations may be obtained directly from Equations (28) by making the proper substitutions.

23.—Volumetric Shrinkage Coefficient.—It was explained in Section 5 that a shrinkage of volume takes place when two salt solutions of different densities are mixed. In many cases this shrinkage is relatively small, but there are cases where it would have to be taken into account when errors of less than 1% are of consequence, as, for example, where equal volumes of strong salt solution and distilled water are mixed.

It will appear presently that the total shrinkage of volume is only a relatively small fraction of the volume of the stronger of the two solutions which are mixed. Hence it will always be convenient to consider that the resultant volume is equal to the volume of the weaker solution plus a certain fraction of the original volume of the stronger solution.

Thus, if q is the volume of the stronger solution and Q_1 that of the weaker, the resultant volume may conveniently be written

$$Q_2 = Q_1 + kq \quad \ldots\ldots(58)$$

where k is a positive fraction which will be found to approximate unity more or less closely in any case. It will be shown that the minimum value which k can have is approximately 0.96.

If Equation (58) is divided by q the result will be

$$R = r + k \quad \ldots\ldots(59)$$

which is an equation of fundamental importance.

Now, from Equation (48),

$$Q_2 = Q_1 \frac{d_1}{d_2} + q \frac{d}{d_2}$$

$$= Q_1 + \left(Q_1 \frac{d_1}{d_2} - Q_1\right) + q \frac{d}{d_2}.$$

Therefore

$$\left.\begin{aligned} Q_1 + k\,q &= Q_1 + \left[\left(r\,\frac{d_1}{d_2} - r\right) + \frac{d}{d_2}\right]q \\ \text{or} \qquad k &= r\left(\frac{d_1}{d_2} - 1\right) + \frac{d}{d_2} \end{aligned}\right\} \quad \ldots\ldots(60)$$

which gives the value of k in terms of the densities of the two solutions and their resultant mixture.

By analogy

$$k = r\left(\frac{c_1}{c_2} - 1\right) + \frac{c}{c_2} \quad \ldots\ldots(61)$$

By taking the last two of Equations (49) with Equation (59), we have

$$\left.\begin{aligned} R &= r + k \\ Rd_2 &= rd_1 + d \\ Rc_2 &= rc_1 + c \end{aligned}\right\} \quad \text{or} \quad \left\{\begin{aligned} R &= r + k \\ RD_2 &= rD_1 + 1 \\ RC_2 &= rC_1 + 1 \end{aligned}\right\} \quad \ldots\ldots(62)$$

from which, by eliminating R and r, we may derive a value for k in terms of densities and concentrations, thus

$$k = \frac{C_2 - C_1 - (D_2 - D_1)}{C_2 D_1 - C_1 D_2} \quad \ldots\ldots(63)$$

which may also be easily obtained by noting from above that $k = R - r$, and then taking the difference between the two Equations (53).

Therefore k may be computed by any one of Equations (60), (61), or (63). In making the calculations, it is necessary, of course, to make use of the physical properties of the salt solution, as given in Table 1 or Plates XXXIII, XXXIV, and XXXV. It must be remembered that Equations (1), (2), (3), and (4) are limited to very dilute solutions.

By applying Equation (60) for various ratios of mixture, r, at different temperatures, Table 3 has been computed for two strengths of salt solution and for ratios of mixture from 1 to infinity. The correctness of the figures depends on the accuracy of Landolt and Börnstein's tables. If the table is in error, or if the salt solution contains impurities, the figures will include a corresponding error,

though this error, in many cases, will not be large. It may clarify matters to reiterate that the table has been computed for the water of the St. Lawrence River as it reached the power-house during the turbine tests considered herein. The tabular values of k, therefore, will not exactly check the values obtained in Section 5.

TABLE 3.—VOLUMETRIC SHRINKAGE COEFFICIENT FOR THE WATERS OF THE ST. LAWRENCE RIVER DURING THE TURBINE TESTS CONSIDERED IN THIS PAPER.

(*A*) { Concentration of salt solution = 300 grammes per liter.
Concentration of canal water = 0.014 gramme per liter.

NOTE.—The figure in the fourth decimal place is likely to be in error.

The relative shrinkage of volume on mixing the two salt solutions, as computed in Section 5, is given by the equation:

$$\frac{\Delta Q}{Q} = \frac{1 - k}{r + 1},$$

where ΔQ is the shrinkage of the mixture from the sum, Q, of the volumes of the two components before being mixed.

In computing the values of p_2, it will be of advantage to notice that

$$p_2 = \frac{r c_1 + c}{r d_1 + d} \qquad (64)$$

which may be derived from Equations (8), Section 9, by putting $w = q\,d$, $p = c \div d$, etc.

To facilitate interpolations for values of k, Fig. 1 has been prepared; its use will be understood without further explanation.

COEFFICIENT OF VOLUMETRIC SHRINKAGE
FOR
MIXTURES OF SALT SOLUTION AND CANAL WATER.

The coefficient is the fraction by which the volume of the stronger solution must be multiplied to obtain the volume which when added to the volume of the weaker gives the volume of the subsequent mixture.

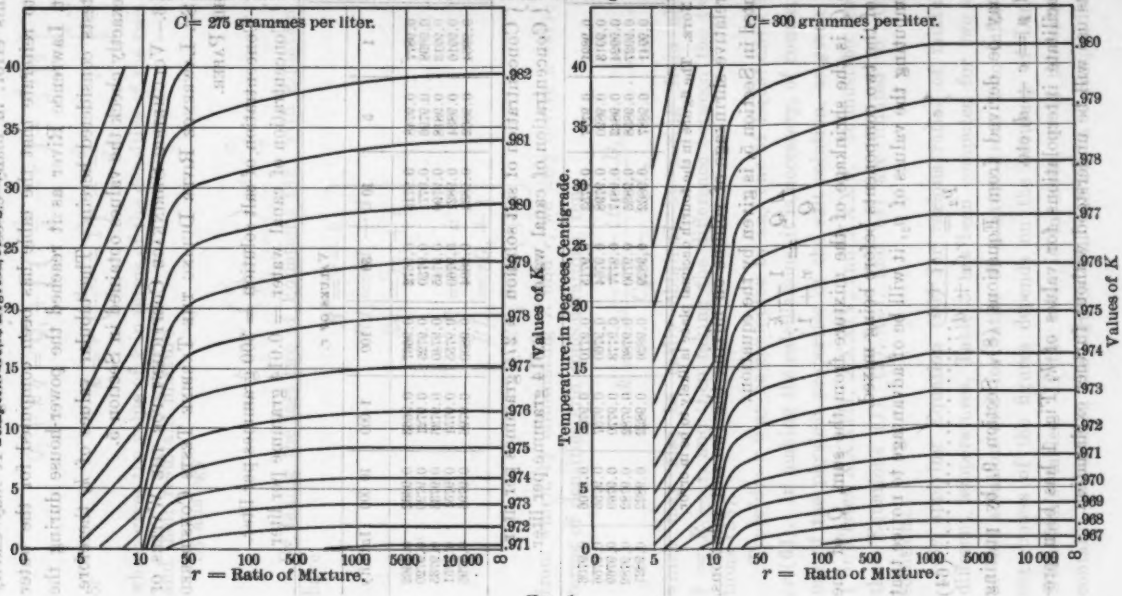

FIG. 1.

24.—Minimum Coefficient of Shrinkage.—It was stated in Section 23 that the least value of k is approximately 0.96. It will be seen from an inspection of Table 3 that the coefficient decreases when the density of the strong salt solution increases, when r increases, and when the temperature falls, the lowest tabular value being about 0.966. If we limit the temperature to zero, and take the strongest salt solution at that temperature, we may find, by Equations (60), (61), or (63), the value of k for any ratio of mixture. The least value will be for an infinite ratio, thus the problem is to find the limit of k when r is made to approach infinity as a limit.

Take, for example, Equation (63), noting that

$$C_1 = P_1 D_1, \text{ etc. (see Equations (6) and (50))} \quad \ldots\ldots(65)$$

$$D_1 = D_0 + n \frac{c}{d^2} P_1, \text{ etc. (see Equations (1) and (50))} \quad \ldots\ldots(66)$$

$$\begin{aligned} C_2 - C_1 &= P_2 D_2 - P_1 D_1 \text{ (from Equation 66)} \quad \ldots\ldots(67) \\ &= (P_2 - P_1)\left[D_0 + n \frac{c}{d^2}(P_2 + P_1)\right] \\ &= (P_2 - P_1)(D_2 + D_1 - D_0) \end{aligned}$$

$$D_2 - D_1 = n \frac{c}{d^2}(P_2 - P_1) \text{ (Equation (66))} \quad \ldots\ldots(68)$$

$$C_2 D_1 - C_1 D_2 = (P_2 - P_1) D_2 D_1 \text{ (Equation (65))} \quad \ldots\ldots(69)$$

Hence, substituting these values of $(C_2 - C_1)$, $(D_2 - D_1)$, and $(C_2 D_1 - C_1 D_2)$, there may be written, cancelling the common factor $(P_2 - P_1)$,

$$\left.\begin{aligned} k &= \frac{D_1 + D_2 - D_0 - n\frac{c}{d^2}}{D_2 D_1} \text{ (value of } n \text{ in Equations (1) and (2)).} \\ \text{or } k &= \frac{(d_1 + d_2 - d_0)\, d - n\, c}{d_1 d_2} \end{aligned}\right\} \quad \ldots\ldots(70)$$

where n depends on the temperature, as in Equations (1) and (2).

If now, the ratios of mixture and dilution are made to approach infinity as a limit, the value of d_2 will change, approaching d_1 as a limit, while c and n are supposed to remain constant. Therefore, the limit of k is

$$\text{Lt. } k]_{r=\infty} = \frac{(2 d_1 - d_0)\, d - n\, c}{d_1^2} \left\{\begin{array}{l}\text{(salt solution, canal} \\ \text{water, zero degrees.)}\end{array}\right\} \quad \ldots\ldots(71)$$

It will be observed, also, that k will decrease when there is a decrease in the salt content of the water with which the salt solution is

mixed. Hence, to get the least value of the limit of k under the conditions supposed, let the mixture be of the strongest salt solution at 0° cent., with distilled water. That is, $d_1 = d_0$. Therefore

$$\text{Limit } k]_{r=\infty} = \frac{d_0\, d - n\, c}{d_0^2} \left\{ \begin{array}{l} \text{(salt solution, distilled} \\ \text{water, zero degrees.)} \end{array} \right\} \quad \ldots(72)$$

for the case supposed.

On reference to Tables 1 and 2 for numerical values, there may be found for a saturated solution of salt, of 26.4% at 0° cent.,

$$\left. \begin{array}{r} n = 0.772 \\ c = 319.15 \\ d_0 = 0.99987 \\ d = 1.2089 \end{array} \right\} \quad \ldots\ldots\ldots\ldots(73)$$

from which the least value of k is found to be

$$\left. \begin{array}{l} \text{Least value of } k \text{ for a mixture of} \\ \text{saturated salt solution at 0° cent.,} \\ \text{with distilled water at the same} \\ \text{temperature, } r = \infty. \end{array} \right\} \quad 0.9626 \ldots\ldots\ldots\ldots(74)$$

From the fifth column of Table 1 it will be found that the volume of distilled water required to make a liter of saturated salt solution at 0° cent. is 889.87. Hence, if Equations (2), Section 3, as derived from Landolt and Börnstein's tables are correct to the limit, it must follow that a molecule of salt always displaces a portion of the water in which it is dissolved, however dilute the solution may be. If the curves of Plate XXXIII approach a slope of 45° or more, when the concentration approaches zero, which does not appear to be the case, this statement would not be true.

Otherwise the limit of k, in Equation (74), would necessarily be 0.88987, the volume of distilled water in a cubic centimeter of saturated salt solution at 0° cent.

Of course, the same limit could be calculated from either Equations (60) or (61).

An actual observation of the value of k was made during the calibration of the solution tank by the chemical method on November 23d, 1914. (See Tables 34 and 35.) The tank was first filled with canal water to the point marked A on the calibration scale of the gauge-board, shown at A on Plate XXXVII. A calibrator full of strong

salt solution containing about 265 grammes of salt per liter was then discharged into the tank and a thorough mixture was secured by running the circulating pump. The level of the mixed solution in the tank was then found to be at the point, *B*, on the gauge-board. At the left of Plate XXXVII there is a full-sized sketch of the calibration scale.

Now, each division on the scale corresponds to the volumetric delivery of the calibrator. Thus, the space of 1.51 in. from Graduation 12 to Graduation 13 represents the volume delivered by the calibrator at this part of the scale. The rise of level due to the addition of a calibrator of salt solution, observed after a thorough mixture with the canal water originally in the tank, was 1.47 in., as shown on Plate XXXVII. Therefore, the observed value of k in this experiment is $147 \div 151 = 0.973$.

By referring to Table 3, Section 23, and Fig. 1, the value of k, for a ratio of 65 and temperature of 5° cent., which are approximate data from the test, is seen to compare with the observed value above, as follows:

Observed value of k, November 23d, 1914.....0.973
Interpolated tabular value for conditions of test...0.976+

which is within the limit of error probable in reading the elevation of the surface of the solution with the calibration scale. It is not safe, however, to conclude from this one observation that a molecule of salt always displaces a portion of the water in which it is dissolved. The conditions of the test, too, are far removed from the limiting conditions supposed to exist when deriving the limit in Equation (74).

25.—Successive Dilutions.—It has been seen that it is very serviceable, and conducive to accuracy, to dilute the salt solution so as to lead to titrations of samples of the same concentration. It is sometimes convenient to dilute the tail-water to a certain degree of concentration for the same purpose. Hence, it is important to have the relations of the quantities under such circumstances expressed in algebraic form.

From Equations (62), Section 23, we have, for a first dilution, symbolized by R', r', c'_2, etc.,

$$c' = \frac{r' c_1 + c}{R'} \qquad (75)$$

and for a second dilution of this tail-water with a new portion of normal head-water, symbolized by R'', r'', etc.

$$c'' = \frac{r'' c_1 + c'}{R''} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (76)$$

Substituting the value of c' from Equation (75), we derive

$$c'' = \frac{r'' c_1 + \dfrac{r' c_1 + c}{R'}}{R''} = \frac{R' r'' c_1 + r' c_1 + c}{R' R''}$$

Therefore,

$$c'' = \frac{(R' r'' + r') c_1 + c}{R' R''} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (77)$$

Thus, the whole operation results in a solution which is exactly the same as though the ratio of mixture of normal head-water and salt solution had been $R' r'' + r'$ and the ratio of dilution $R' R''$. Denoting the ratio of mixture and ratio of dilution of the resulting solution by r and R, respectively, the statement may be expressed as follows:

$$\left.\begin{aligned} r &= R' r'' + r' \\ \text{and} \quad R &= R' R'' \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (78)$$

We may, of course, also write

$$r = (r' + k')\, r'' + r' = r' r'' + k' r'' + r' \quad \ldots\ldots\ldots\ldots\ldots\ldots (79)$$

and

$$\begin{aligned} r + k &= (r' + k')\,(r'' + k'') \\ &= r' r'' + k' r'' + r' k'' + k' k'' \quad \ldots\ldots\ldots\ldots\ldots\ldots (80) \end{aligned}$$

We may also deduce relations between k, k', and k''. Thus

$$\left.\begin{aligned} k &= R - r \\ &= R' R'' - R' r'' - r' \\ &= R' k'' - r' \\ &= (r' + k')\, k'' - r' \\ &= k' k'' + r' k'' - r' \\ &= k' k'' + r' (k'' - 1) \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (81)$$

26.—It will aid the comprehension considerably to deduce the relations of Equations (78) by direct reasoning rather than by formulas. Take, for example, a volume, x, of salt solution and dilute with a volume r' times larger, that is, with a volume, $r'x$. Then, by our theory and definitions, the resulting mixture will occupy a volume $k'x + r'x = (r' + k')x$.

Hence 1 liter of the mixture contains $x \div (r' + k')x = 1 \div (r' + k')$ of original salt solution, and $r'x \div (r' + k')x = r' \div$

$(r' + k')$ of normal head-water, the resulting volume of this liter, of course, being

$$\frac{k'}{r' + k'} + \frac{r'}{r' + k'} = 1 \text{ liter.}$$

If, now, a second dilution is made by taking a volume, y, of the first mixture and diluting with a volume r'' times larger, that is, with a volume, $r''y$, we shall have taken the equivalents of

$$\frac{y}{r' + k'} \text{ of original salt solution}$$

and $$\frac{y\,r'}{r' + k'} \text{ of normal head-water}$$

to mix with $r''y$ of normal head-water.

The resulting mixture, therefore, is the same as though

$$\frac{y}{r' + k'} \text{ of original salt solution and } \frac{y\,r'}{r' + k'} + r''\,y$$

of normal head-water had been mixed in one operation.

Therefore,

$$r = \frac{\left(\frac{r'}{r' + k'} + r''\right) y}{\frac{y}{r' + k'}} = (r' + k')\,r'' + r'$$

or

$$r = R'\,r'' + r'$$

the same as in Equations (78), which was proved by algebraic substitutions.

27.—Successive Dilutions in Laboratory.—Suppose now, that, for convenience in laboratory work, the tail-water is diluted in such a manner that r'' liters of normal head-water are mixed with 1 liter of tail-water before taking samples for evaporation. That is, the ratio of mixture is r'' and the ratio of dilution is $r'' + k'' = R''$. Then, if the diluted tail-water is evaporated in the usual manner and the test is reduced as though this had been the actual tail-water, the ratios of mixture and dilution for the actual tail-water can be easily computed from the results, thus,

$$\left.\begin{aligned} r' &= r - R'\,r'' \\ r' &= r - \frac{R}{R''}\,r'' \end{aligned}\right\} \text{(See Equations (78))} \quad \ldots\ldots\ldots (82)$$

which latter is in terms of the laboratory dilution and final ratios of mixture and dilution computed from the modified laboratory procedure indicated previously.

In a similar manner, we may have, directly from Equations (79),

$$\left.\begin{aligned} r' &= \frac{r - k'\,r''}{1 + r''} \\ R' = r' + k' &= \frac{r - k'\,r''}{1 + r''} + k' \\ &= \frac{r}{1 + r''} + \frac{k'}{1 + r''} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (83)$$

but such forms are not entirely independent of the first dilution, as they involve k', or other functions of r' or k'.

Again, from Equations (78),

$$R' = \frac{R}{R''} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (84)$$

which may be used to compute R' when R has been computed from the results of titrations of the samples of diluted tail-water and R'' has been observed. In terms of these same quantities, r' may be expressed as follows, from Equations (82),

$$\left.\begin{aligned} r' &= r - \frac{R}{R''}\,(R'' - k'') \\ &= r - R + \frac{R}{R''}\,k'' \\ &= \frac{R}{R''}\,k'' - k \\ &= \frac{R\,k'' - k\,R''}{R''} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (85)$$

28.—Inverse Dilutions.—Considerable space has been devoted to the theory of mixtures of salt solutions. The study has been necessary to educate the writer sufficiently to enable him to offer very simple proofs of the fundamental volumetric equations depending on ratios of mixture and dilution only. Before proceeding with the discussion it will be well, however, to recall the relations existing between the tail-water and special dilution samples which have been prepared in the laboratory.

The tail-water and special dilution are both mixtures of salt solution with normal head-water, the respective ratios of mixture being r and r' and the respective ratios of dilution R and R'.

As it is the object of the special dilution to reproduce a solution as nearly as possible like the tail-water, we shall always have, more or less closely,

$$R \text{ approximates } R'$$

and

$$r \text{ approximates } r'$$

If it happens that the special dilution is stronger in salt than the tail-water, then $R > R'$ and $r > r'$; but, if the contrary is true, $R' > R$ and $r' > r$. In the former case salt solution may be added to the tail-water until the mixture is just like the special dilution, and in the latter case salt solution may be added to the special dilution until it is just like the tail-water. In each case the quantity of salt solution necessary will depend entirely on the values of R and R', or of r and r', and the quantity of the tail-water, or special dilution, with which it is mixed. In either case the necessary ratio of dilution of salt solution will be indicated by R''.

Such a dilution of salt solution by another solution would convert the latter into a stronger one, whereas, a dilution of the solution with normal head-water would convert it into a weaker one. In this sense the dilution of salt solution with tail-water, or special dilution, will be called an inverse dilution.

29.—Volumetric Equations Involving Ratios Only.—Suppose, first, that the tail-water is weaker in salt than the special dilution, or $R > R'$ and $r > r'$. Let R'' be the ratio of dilution necessary to convert tail-water into special dilution by adding salt solution. Take sufficient tail-water to make the resulting mixture have a volume, R', and therefore contain r' of normal head-water. This must be $\frac{r'}{r} R$ of tail-water, which necessarily contains $\frac{r'}{r}$ of salt solution, as R of tail-water contains r of normal head-water and the resultant mixture must contain only r'. It is also apparent from the premises that the requisite quantity of salt solution to mix with the tail-water is $R' \div R''$ and that the total quantity of salt solution in the resulting mixture must be unity. Therefore,

$$\frac{R'}{R''} + \frac{r'}{r} = 1$$

from which

$$r = \frac{r'}{1 - \frac{R'}{R''}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (86)$$

30.—The tail-water still being weaker than the special dilution, let r'' be the ratio of mixture necessary to convert the former into the latter by adding salt solution. Take a volume, R, of tail-water, which contains r of normal head-water and 1 of salt solution. It will require $R \div r''$ of salt solution to reduce the mixture to the condition of special dilution, as tail-water is being mixed with the salt solution and r'' is the ratio of mixture. Thus, the resulting mixture contains $1 + \frac{R}{r''}$ of salt solution and r of normal head-water. The resulting mixture, however, is exactly the same as the special dilution. Therefore,

$$\frac{r}{1 + \frac{R}{r''}} = r' \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (87)$$

31.—From Equations (86) and (87) it is clear that

$$\left(1 + \frac{R}{r''}\right)\left(1 - \frac{R'}{R''}\right) = 1 \quad \ldots\ldots\ldots\ldots\ldots\ldots (88)$$

and that the quantity of salt solution required to reduce a solution the ratio of mixture of which with the same salt solution is r to a stronger one having a ratio of r' is such that

$$\left.\begin{aligned} R'' &= \frac{R'}{1 - \frac{r'}{r}} \\ \text{and} \quad r'' &= \frac{R}{\frac{r}{r'} - 1} \end{aligned}\right\} \quad (r > r') \quad \ldots\ldots\ldots\ldots (89)$$

32.—Reciprocal Dilutions.—It will be seen by reference to Section 25 that the second dilution with normal head-water there discussed converts special dilution into tail-water; and the dilution with salt solution examined in Sections 29 and 30 returns the mixture to its original condition as regards its relative composition. A pair of dilutions thus related may be called a pair of reciprocal dilutions.

It is clear from Section 25, Equations (78), that $R'r''$ is the quantity of normal head-water necessary to convert R' of special dilution to the condition of tail-water, and, from Section 30, that $R \div r''$ of salt solution will return the mixture to its original condition of special dilution in which the ratio of mixture is r'. Therefore the quantity, $R'r''$, of normal head-water and the quantity, $R \div r''$, of salt solution must be mixed in the same ratio as the special dilution, or

$$\left.\begin{aligned} \frac{R'\,r''}{\frac{R}{r''}} &= r' \\ \text{and} \qquad r''\,r'' &= R''\,r' \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (90)$$

From Section 29, if $\frac{r'}{r}R$ of tail-water is mixed with $\frac{R'}{R''}$ of salt solution, the mixture will be of volume, R', will contain a unit volume of original salt solution, and r' of normal head-water. Consequently, the $\frac{r'}{r}R$ of tail-water must have contained r' of normal head-water and $1 - \frac{R'}{R''}$ of salt solution. Therefore, using Equations (78),

$$\frac{r - R'\,r''}{1 - \frac{R'}{R''}} = r$$

from which

$$R''\,r'' = r \qquad (r > r') \ldots\ldots\ldots\ldots\ldots (91)$$

Expanding the product in Equation (88), there results

$$\frac{R}{r''} - \frac{R'}{R''} - \frac{R'\,R}{R''\,r''} = 0 \ldots\ldots\ldots\ldots\ldots (92)$$

Hence,

$$\left.\begin{aligned} \frac{R}{r''} &= \frac{\frac{R'}{R''}}{1 - \frac{R'}{R''}} \qquad (r > r') \\ \frac{R'}{R''} &= \frac{\frac{R}{r''}}{1 + \frac{R}{r''}} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots (93)$$

which may also be written

$$\left.\begin{aligned} \frac{R}{r''} &= \frac{1}{\frac{R''}{R'} - 1} \\ \frac{R'}{R''} &= \frac{1}{\frac{r''}{R} + 1} \end{aligned}\right\} \quad (r > r') \qquad \ldots\ldots\ldots\ldots\ldots\ldots (94)$$

From Equations (90) we have, as $R'' - r'' = k''$,

$$k'' = \frac{R'\,r - R\,r'}{r - r'} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (95)$$

which reduces easily to

$$k'' = \frac{k'\,r - k\,r'}{r - r'} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (96)$$

As the greater r must be associated with the smaller k (see Table 3 or Fig. 1), it must follow that

$$k'' > k \text{ and } k'' > k'.$$

When r and r' are nearly equal, and relatively large, it is clear that $k'' = k = k'$, practically. Indeed, the limit of k'' for fixed temperatures is $k' - r' \frac{d\,k'}{d\,r'}$, when r approaches r' as a limit. Fig. 1 shows that $r \frac{d\,k}{d\,r}$ is small, relatively to k, for all likely values of r.

33.—Since the discussion of Section 25, it has been assumed generally that the tail-water was a weaker solution than the special dilution, that is, that $r > r'$. If the contrary is true, and $r' > r$, then it would be necessary to dilute the tail-water with normal head-water to convert it to a solution like the special dilution, and to introduce salt solution into the special dilution to reproduce the conditions of tail-water. The foregoing equations for the successive and inverse dilutions would still hold, all the reasoning applying exactly as before, provided that r' and r, and R' and R are mutually interchanged in the equations, while the definitions of R'', r'', R'' and r'' would require a corresponding modification agreeable to the changed sense of the operations.

34.—*Volumetric Equations Involving Concentrations Only.*—From Equations (62),

$$\left.\begin{aligned} R &= r + k \\ R\,C_2 &= r\,C_1 + 1 \end{aligned}\right\} \qquad \ldots\ldots\ldots\ldots\ldots\ldots (97)$$

from which,

$$\left.\begin{aligned} r &= \frac{1 - k C_2}{C_2 - C_1} \\ R &= \frac{1 - k C_1}{C_2 - C_1} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (98)$$

in terms of concentrations which are relative with respect to the concentration of the strong salt solution.

In terms of the actual concentrations,

$$\left.\begin{aligned} r &= \frac{c - k c_2}{c_2 - c_1} \\ R &= \frac{c - k c_1}{c_2 - c_1} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (99)$$

which are derived from Equations (98) by multiplication by c. Thus

$$c_1 = c\, C_1.$$

These forms, however, are subject to the errors of titration which affect c_1 relatively to c and c_2, as has been explained in Sections 15 and 16. In order to overcome this objection, the method of special dilutions is available, as described in the sections referred to and elsewhere in this paper.

35.—The preceding discussions enable us to write out at once the equations pertinent to the method of special dilutions and involving only the concentrations and one coefficient of shrinkage. These equations are the most convenient where the samples are measured volumetrically, but, as has been explained in Section 10, the equations of Sections 13 and 14 are much better adapted to the requirements of turbine testing. Resuming the assumption that $r > r'$, the definitions of Sections 29 and 30 require that

$$\left.\begin{aligned} r'' &= \frac{c - k'' c'_2}{c'_2 - c_2} \\ R'' &= \frac{c - k'' c_2}{c'_2 - c_2} \end{aligned}\right\} \quad (r > r') \quad \ldots\ldots\ldots\ldots\ldots\ldots (100)$$

$$0.96 < k'' < 1$$

which are the same in form as Equations (99).

But, if the assumption is that $r' > r$, we must have

$$\left.\begin{aligned} r'' &= \frac{c - k'' c_2}{c_2 - c'_2} \\ R'' &= \frac{c - k'' c'_2}{c_2 - c'_2} \end{aligned}\right\} \quad (r' > r) \quad \ldots\ldots\ldots\ldots\ldots\ldots (101)$$

Hence, changing the assumption is equivalent to substituting $-r''$ for R'' and $-R''$ for r'' in Equations (100) or (101).

Now, under the assumption that $r > r'$, and consequently that $c'_2 > c_2$ we have, by Equations (86) and (100),

$$\left.\begin{aligned} r &= \frac{r'}{1 - \frac{R'}{R''}} \\ \text{or} \qquad & \qquad (c'_2 > c_2) \\ r &= \frac{r'}{1 + R' \frac{c_2 - c'_2}{c - k'' c_2}} \end{aligned}\right\} \ldots\ldots\ldots\ldots (102)$$

But, under the assumption that $r' > r$, and consequently that $c_2 > c'_2$, we have, interchanging r and r', and putting R' for R, by Equations (87) and (101),

$$\left.\begin{aligned} r &= \frac{r'}{1 + \frac{R'}{r''}} \\ \text{or} \qquad & \qquad (c_2 > c'_2) \\ r &= \frac{r'}{1 + R' \frac{c_2 - c'_2}{c - k'' c_2}} \end{aligned}\right\} \ldots\ldots\ldots\ldots (103)$$

We have, by Equations (93),

$$R = \frac{\frac{R'}{1 + \frac{k''}{r''}}}{1 - \frac{R'}{R''}}$$

which reduces easily to

$$\left.\begin{aligned} R &= \frac{R'}{1 + \frac{k'' - R'}{r''}} \\ \text{or} \qquad & \qquad (c'_2 > c_2) \\ R &= \frac{R'}{1 - (k'' - R') \frac{c_2 - c'_2}{c - k'' c'_2}} \quad \text{(see Equations (100))} \end{aligned}\right\} \ldots (104)$$

But when $r' > r$, we have, by substituting r for r', R for R', and *vice versa*, by Equations (93) and 101),

$$R = \frac{\frac{R''}{r''} R'}{1 + \frac{R'}{r''}}$$

or

$$R = \frac{R'}{1 - (k'' - R') \frac{c_2 - c'_2}{c - k'' c'_2}} \qquad (c_2 > c'_2) \qquad \text{.....(105)}$$

Therefore, it is proved generally, whether $c_2 > c'_2$, or the contrary, that the general equations for r and R by the method of special dilutions are

$$r = \frac{r'}{1 + (r' + k') \frac{c_2 - c'_2}{c - k'' c_2}}$$

$$r = \frac{R' - k'}{1 + R' \frac{c_2 - c'_2}{c - k'' c_2}} \qquad \text{(General formulas, method of special dilutions.)}$$

$$r = \frac{r'}{1 + R' \frac{c_2 - c'_2}{c - k'' c_2}} \qquad (1 > k'' > 0.96) \qquad \text{....(106)}$$

$$R = \frac{R'}{1 + (R' - k'') \frac{c_2 - c'_2}{c - k'' c'_2}}$$

$$R = \frac{r' + k'}{1 + (r' + k' - k'') \frac{c_2 - c'_2}{c - k'' c'_2}}$$

36.—Equations (106) may, of course, be deduced in numerous other ways, for example, by making use of Equations (27) of Section 14, Equations (38) of Section 18, Equations (53) of Section 22, and the relations of Equations (100) and (101) of Section 35.

37.—Constancy of Salt Content in Head-Water.—Similar to Equations (28) of Section 14, and Equations (45) of Section 20, are the equations derived from either Equations (62) of Section 23, or Equations (98) and (99) of Section 34, when special dilutions are

made up in the laboratory, and the normal head-water titration is calculated instead of observed, thus,

$$\left.\begin{aligned} c_1 &= \frac{R'\,c'_2 - c}{r'} \quad \text{(Value } c_1 \text{ to check constancy of head-water content of salt.)} \\ r &= \frac{c - k\,c_2}{c_2 - c_1} \quad \text{(General formulas for method of special dilutions.)} \\ R &= \frac{c - k\,c_1}{c_2 - c_1} \quad (1 > k > 0.96) \end{aligned}\right\} \cdots\cdots (107)$$

The special dilutions eliminate the unbalanced evaporations for c_1, as compared with the evaporations for c_2.

Of course, it has not been forgotten that we may substitute v for c in these equations, so as to introduce the titrations per liter of the various solutions, instead of the concentrations. Indeed, by slight modifications of these formulas, the actual titrations, t, t_2, etc., may be substituted, as was illustrated in Equations (33) of Section 16, and as will be shown in the discussion of the theory involved in Equations (27), (28), (39), (44), (45), (106), (107), (108), and others of similar nature. This discussion appears in Section 45.

38.—Volumetric Equations Involving Densities Only.—Owing to the relations discussed in Section 21, there may be written, by analogy,

$$\left.\begin{aligned} r &= \frac{r'}{1 + R'\,\dfrac{d_2 - d'_2}{d - k''\,d_2}} \quad (1 > k'' > 0.96) \\ R &= \frac{R'}{1 + (R' - k'')\,\dfrac{d_2 - d'_2}{d - k''\,d'_2}} \end{aligned}\right\} \cdots (108)$$

which might be used for the purpose of determining volumes of discharge when facilities are at hand for determining densities with the requisite precision.

39.—Color.—Instead of d relating to the specific quantity of matter, or quantity of chemical, present, it may relate to the intensity of any other property, such, for example, as color, which can be diffused throughout the volume of the liquid, the term, d, being in that case a measure of the quantity of coloring matter necessary to give the liquid a measurable or comparable tint. In such case the tints due

to d_2 and d'_2 can be made to agree exactly, so that the second term of the denominator vanishes and we have simply

$$R = R' \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (109)$$

where R' is the only quantity necessary to measure, the colors of the tail-water and special dilutions being exactly matched. A colorimeter of special construction will evidently facilitate the determinations of R', and therefore of R.

40.—Electro-Metric Methods.—Time will not be taken up in entering into the great variety of methods which may be used in gauging by "dosing" the feed-water of a turbine. Suffice it to state that electro-metric methods are also being studied at the present time in various parts of the world, notably by Dr. Mellet and P. Dutoit, in Switzerland. The writer also has had made some tests of this character which seem promising.

Dr. Mellet's pamphlet, "Les Jaugeages par Titration Physico-Chemique," an extract from *Bulletin Technique* de la Suisse Romande, February 10th, 1915, page 25, gives the results of several gaugings by this method, with an account of the nature of the processes.

The writer's method of applying the conductivity test is: First, determine the conductivity of the tail-water; secondly, prepare a special dilution of the same salt solution which was used in the test with normal head-water, approximating as nearly as possible the actual ratio during the test; thirdly, with the same electrodes and the same electrical equipment used with the tail-water, determine whether the conductivity of the special dilution is greater, or less, than that of the tail-water; fourthly, measure from a burette the quantity of salt solution, or normal head-water, as the case may be, necessary to equate exactly the conductivity of the special dilution to that of the tail-water, the burette discharging directly into the special dilution, which is constantly stirred, until the electrical indicator shows that the two conductivities are equal; fifthly, the known ratio of dilution of the special dilution, determined from the measured quantities of the components, is then the required ratio of dilution for the test; sixthly, this ratio multiplied by the rate of discharge of the salt solution during the test gives the discharge of the turbine. Of course, the method of weights as against the method of volumes has the same advantages when measurements are made electrically as when they are made chemically.

PART II.

ERRORS.

Summary.

41.—Part II discusses at length the errors of the method and the procedure for their elimination. Corrections have been determined and tabulated for the method of unbalanced evaporations.

Incidentally, the method of balanced evaporations, or special dilutions, leads to an independent determination of the error produced by unbalanced evaporations, and proves that the writer's method of correcting the results by the latter method is correct.

A system of group titrations is devised, for the purpose of eliminating a large variety of errors.

The effect of non-uniformity of mixture of the chemical with the feed-water is shown to be less than many have heretofore supposed. This was shown in the tests by throwing the heavier concentration first to one side of the raceway and then to the other. The properly weighted concentrations give results which plot on a line, while the unweighted concentrations do not exhibit such discrepancies as would be a serious matter in tests of ordinary precision. In the best results, on Unit No. 13, the arithmetical mean concentrations would have served almost as well as the weighted mean.

The centrifugal pump is proved to be an excellent mixer of salt solution and canal water. Tests on such pumps can be executed with the utmost precision by the chemical method. Indeed, it is doubtful whether a better method can be found for the testing of pumps.

The weights for averaging the tail-water concentrations were determined by current meters in the tail-race. The still-water ratings, without correction, were used, but it is likely that some better method can be devised for determining weights.

The difficulties encountered in securing representative tail-water samples are related, with the means adopted for removing all uncertainty in this respect.

The method of designing and installing efficient sprinkler mixing systems is discussed, with the results of experiments bearing on sprinklers and perforations.

Pipette calibrations of an unusual character are given which show the combined and separate effects of temperature and concentration of

salt solution on the discharge of these instruments. It has been the practice, even by the United States Bureau of Standards, to calibrate a pipette at one temperature and then to assume that the changes in discharge due to changes in temperature are equal to the corresponding changes in volume of the pipette, thus disregarding the effects on the discharge of those properties of the contained liquids which change with the temperature.

It is shown herein that the change in discharge due to a change in temperature is entirely distinct from the change in volume of the pipette due to the same change in temperature, and that the combined effects of viscosity, surface tension, cohesion, and capillary action in general affect the discharge to a very much greater extent. The total change in discharge is several times the change in volume of the pipette. Isograms giving the discharge of pipettes for salt solutions of all concentrations at various temperatures are given as a ready means for determining the discharge.

The calibrations of flasks are given at all working temperatures, and rules are stated for effecting a perfect mixture by shaking the flasks containing mixtures of salt solutions and water. It does not appear that it is generally known how many times an ordinary liter flask must be inverted and shaken to secure a uniform mixture. A failure of the chemists to secure accurate mixtures during the early tests necessitated a special investigation to determine this question.

It is proved that there is no systematic error of any consequence in the chemical procedure developed and used during the tests. This conclusion is proved by the close agreement between the chemical and gravimetric calibrations of the salt solution tanks. The tests are of greater value on account of the unfavorable conditions under which they were executed than they would have been under the more propitious conditions of an extremely painstaking laboratory process.

It is shown that the wooden salt solution tank used during the tests was remarkably constant in volume, probably not changing its capacity by one-tenth of 1% during the entire season.

A method of eliminating the error introduced into the computed efficiency of a turbine by reason of an error in the density of the feed-water is given, and also a method for obviating the necessity for determining the density of the feed-water. That is, the density of feed-water has been entirely eliminated from the calculation.

The weight of the salt injected into the feed-water may be neglected in most cases.

The question is raised as to the correct method of determining the head acting on a turbine. It is shown that the velocity-head should be taken into account, and simple methods for its determination are discussed.

The effect on the tail-race concentration, and therefore on turbine efficiency, of variations of discharge and power during a test have been determined, and are shown to be negligible where the variations are less than certain limiting variations.

The relation of volume- to time-averages is discussed, so that, with a time-average concentration, a volume-average may be computed, and *vice versa*. Time-averages are shown to be accurate enough for most purposes. A device is suggested for determining volume-averages.

The sources of error in chemi-hydrometry may be classified as follows:

1.—*Initial Content of Chemical.*—There may be chemicals in the stream initially which react with the standard; or the dosing chemical may be affected by them.

2.—*Variability of Initial Content.*—The initial content of a chemical may be variable, and this variation may be appreciable from minute to minute.

3.—*Variability of Standard Chemical.*—The character of the standard, and consequently the equivalent weights of other chemicals, may change during a series of chemical analyses.

4.—*Indicator.*—The indicator used in volumetric analyses may act on the standard chemical. This is the case to an appreciable extent when chromate of potassium and silver nitrate are used.

5.—*Excess of Standard.*—An additional excess of standard chemical will usually be required to effect a definite determination of the end of the reaction.

6.—*Distribution of Chemical.*—The chemical is not likely to be distributed uniformly throughout the mass of the liquid to be measured, either as to time or place, except in the case of relatively small quantities of liquid.

7.—*Temperature Effects.*—The temperature during a test, or series of tests, and at the time of the ensuing treatment of samples in the laboratory, may be different at different times and places, thus introducing changes in the capacities of the measuring instruments, and corresponding changes in the volumes and properties of the various solutions used.

8.—*Changes in Calibrations.*—There may be other circumstances which cause changes in the calibrations of the various instruments, such for example as a change in the volume of the tank from which the dosing chemical is discharged and measured.

9.—*Time.*—Even if the watches have been carefully regulated and rated, there may be errors in observing, such, for example, as the personal error of an observer.

10.—*Density of Feed-Water.*—In turbine testing an error will be made if the density of the feed-water entering into the efficiency calculations is in error. This density may be determined or the error may be eliminated by the method of counter errors, explained in the sequel.

11.—*Weight of the Chemical.*—A similar error to that preceding will be made if the weight of the chemical injected into the head-water is not taken into account. However, in most cases this will be inappreciable.

12.—*Additions or Abstractions of Chemical.*—There may be additions or abstractions of chemical between the dosing and sampling stations, due either to natural causes, such as mineral springs, or to artificial causes, such as the operation of industries between the stations.

13.—*Additions or Abstractions of Water.*—There may be additions or abstractions of water between the stations due to natural or artificial causes.

14.—*Error in Tables.*—There may be errors in the physical constants used in the computations. For example, there may be errors in Table 1.

15.—*Errors in Theory.*—The theory may not be complete, or it may be fundamentally wrong. For example, it is shown later that there is an error in using Equations (17) of Section 11, without correcting v_1 for the error of titration, whereas,

Equations (27) and (28), Sections 13 and 14, are correct in this respect when the data are correctly observed.

16.—*Air in Feed-Water.*—On referring to Section 73, it will be seen that the density of the feed-water may be eliminated. It is also clear that the chemical method of measuring discharge does not include the volume, or weight, of any air, which may be entrained in the water temporarily as it passes the turbine.

42.—Net Error Due to Imperfect Theory.—In discussing the foregoing errors, it will be of advantage first to take up the net error due to imperfect theory, after which a detailed examination of the separate errors will be made.

In order to examine the theory, let

c_s = concentration of the standard chemical;

v = volume of the standard required to titrate a unit volume of sample;

V = volume of sample titrated;

e = equivalent of the dosing chemical, salt for example, per gramme of the standard chemical. In theory this will be the ratio of molecular weights, but in practice it will vary from such a ratio, due to various sources of error;

t = actual titration of a sample which is not exactly one unit in volume, thus $v = t \div V$, $v_2 = t_2 \div V_2$.

Then, for example, theoretically, we must have such equalities as

$$\left.\begin{aligned} c_2 &= \frac{t_2 c_s e}{V_2} \\ c &= k \frac{t_2 c_s e}{V_2} \end{aligned}\right\} \quad \text{or} \quad \left.\begin{aligned} Q &= q \frac{t_2 c_s e}{V_2} - \frac{t_1 c_s e}{V_1} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (110)$$

where e is strictly the ratio of chemical equivalents; but, in actual cases, it will seldom be found that such expressions constitute actual equalities; one side or the other will be the greater. Such a failure of theory may result from one or more sources of error.

It must not be supposed, therefore, that the ratio of chemical equivalents, e, deduced from the atomic weights of the elements involved, can be used with any degree of reliability in practical cases. Even where the chemicals are pure, there will be required a certain

excess of standard chemical in order to act on the indicator, and this excess will vary with circumstances. This is equivalent to saying that the practical value of e is variable to a slight extent.

It is necessary, therefore, to determine by actual observation what the net effect of the errors is, in any particular case, so that the observed discharge can be corrected; or, measures must be adopted so that the errors will be eliminated or reduced to inappreciable magnitudes.

43.—Practical Determination of Net Error of Titration for Equations (14), (17), (46), (53), (98), and (99).—Take Equations (99), Section 34, for example. These are virtually the same as Equations (53), Section 22, Equations (46), Section 20, or Equations (14) and (17), Section 11. If we substitute $Q_1 \div q$ for r, and $(Q_1 + kq) \div q$ for R, we have

$$Q_1 c_1 + qc = (Q_1 + kq)c_2 \ldots\ldots\ldots\ldots\ldots\ldots (111)$$

In terms of silver nitrate, or other chemical, this may be written

$$Q_1 v_1 + qv = (Q_1 + kq)v_2 \ldots\ldots\ldots\ldots\ldots\ldots (112)$$

v, v_1, and v_2 being the quantities of silver nitrate required per liter of the samples as used in the tests. Hence, if t, t_1, and t_2 are the actual quantities of silver nitrate required for the corresponding samples, we shall have

$$v = \frac{t}{q}, \quad v_1 = \frac{t_1}{Q_1}, \text{ and } v_2 = \frac{t_2}{Q_1 + kq} \ldots\ldots\ldots\ldots (113)$$

Substituting these values in Equation (112), we derive

$$t_1 + t = t_2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (114)$$

as might naturally be inferred without reference to Equation (112). That is to say, if three samples are prepared, consisting, respectively, of Q_1 of normal head-water, q of salt solution, and a mixture of Q_1 of normal head-water and q of salt solution, we should have the relation shown by Equation (114) between the titrations, because the last of the three samples is simply a mixture of samples exactly like the first two.

But, if the relation of Equation (114) fails to hold in actual trial, the fact will prove that the theory is incomplete, involving a systematic error, or that the methods do not eliminate the errors of titration. Moreover, if the samples, Q_1 and q, are of the same size as those

corresponding in the actual test, the difference between $(t_1 + t)$ and t_2 will determine the error due to the titration of samples of these sizes and concentrations.

A number of tests were made in this manner to determine whether the theory involved in the foregoing equations was exact or only approximate, with the result that the latter was shown to be the case. Table 4 exhibits the results which have been collected for this purpose. It must be impressed on the mind that these data are not derived from refined laboratory experiments, but were made in a rough field laboratory, hastily equipped in an old pumping station and storeroom, where there was more or less confusion resulting from the operation of large industrial plants in the immediate vicinity. Moreover, the chemical work was all done on a wholesale plan, under considerable pressure, so that no great attention could be paid to the details connected with any one operation. This was necessary in order to give capacity to the chemical laboratory, otherwise the large number of evaporations and titrations necessary could not have been executed.

On the other hand, it must be equally impressed on the mind that the best work done in this laboratory will undoubtedly rank with the best commercial laboratory practice. In fact, much that has been accomplished there will compare favorably with chemical research work of much greater pretension. It may be safely stated that the averages of half a dozen titrations as usually performed there will check the average of another similar set well within one-tenth of 1%, one-twentieth of 1% having been the error frequently observed. We have read much correspondence by eminent chemists on the subject of the accuracy of silver nitrate titrations for chlorine, and the accuracy obtained in our titrations will be better appreciated when it is stated that chemists as a rule do not rely on such titrations as being accurate to within 1 or 2 per cent. We have, however, to thank Dr. Mellet for his extended studies, which have resulted in a determination of the proper strengths of the solutions necessary to secure a degree of accuracy well within one-tenth of 1 per cent.

Nor is the degree of accuracy attained in the turbine tests to be inferred from the test titrations of Table 4, for most of these test titrations were crowded in at such times as the chemists chanced to be under less pressure of work than usual, and each series of test titrations, therefore, represents a break in the usual laboratory pro-

cedure, and must be looked on as being conducted in a less systematic and efficient manner than the regular tests.

In studying the test titrations of Table 4 it will be best first to examine the work done in August, as that done in July was at a time when the chemists were less accustomed to their duties, and the facilities were not so well arranged as at a later time.

The tests of August 7th and 17th were arranged so that a sample of normal head-water consisted of a 500-c.c. flask filled to the graduation mark with this water. A sample of salt solution consisted of the quantity discharged from a 10-c.c. pipette, according to the directions set forth in the rules for the laboratory procedure, given in Section 88. A sample of dosed tail-water consisted of a 500-c.c. flask of normal head-water and a 10-c.c. pipette of salt solution mixed in a flask. It was scrupulously observed that the same flask and the same pipette were used throughout by any chemist in making up a set of three such samples. The salt solution was made of such a strength that the titration of this sample would run about half what it did in the usual test, and the normal head-water and dosed tail-water samples would run about as the usual ½-liter samples.

In the case of the tests of August 25th and September 26th to 28th, a somewhat different procedure was adopted. The salt solution was of about double the strength of that used on August 7th and 17th, and a sample of dosed tail-water was composed of approximately the half part of a mixture of 10 c.c. of salt solution and a liter of normal head-water. As before, only one flask and one pipette were used by any chemist in making up a set of samples. The exact division of the mixture of salt solution and dosed tail-water into ½-liter samples, was not attempted, thus leaving apparent inconsistencies among the records of the titrations of dosed tail-water samples, for these tests. The sum of the titrations of mates, however, is quite consistent from pair to pair, considering that no extra pains were taken during the work. In fact, the work was not as good as that done in the regular tests, as has been explained. Thus, the titrations of the samples on August 25th and September 26th to 28th were arranged to represent, as nearly as convenient, the actual titrations of a regular test.

As a consequence of the method of making up the samples and conducting the titrations, the sum of the normal head-water and salt

solution titrations, of any set, should, theoretically, be equal to the titration of the dosed tail-water sample of the same set. For example, on August 7th, we have 13.194 + 27.756 = 40.950, as compared with 40.785. Thus, the sum of the normal head-water and salt solution titrations exceeds that of the dosed tail-water by (40.950 — 40.785) = 0.165, an error of about 0.4% of the dosed tail-water titration.

This error is due to the fact that the concentration of the three samples is not the same. Indeed, the samples should be exactly alike as to all their characteristics, if the error of titration is to be eliminated. Dr. Mellet has accomplished the equation of the concentrations by proportioning sizes, dilutions, and evaporations in such a way that all samples will titrate alike. This, however, removes only a part of the difficulty, for the evaporations of the tail-water and normal head-water will necessarily be unbalanced, and the salt solution samples are dilutions with distilled water, instead of evaporations for concentration. As an example, it may be seen that it would have been necessary to evaporate about three times as much normal head-water as tail-water, in the tests now being discussed, in order to equate titrations, thus, perhaps, eliminating at least a part of the error detected above and observable in all the other tests.

Unfortunately, however, the equation of titrations requires unbalanced evaporations, and does not equate the errors of titration entirely, because there are other characteristics than concentration which must be equated simultaneously, as has already been pointed out in the theory which has been developed by the writer, in order to eliminate completely the errors of titration. There are organic and other substances in the normal head-water, which, when concentrated, operate in an entirely different manner to modify the titration of a sample of this solution as compared with a sample of either the dosed tail-water, brought to the same concentration, or the dilute salt solution sample, which contains no organic or other substances than the chemicals used in the test.

These differences are so marked that a little experience, even with such clear water as that of the St. Lawrence River, enables a person to know the class to which a particular sample belongs by mere inspection of its appearance. When evaporated in a casserole to a concentration of about 6 mg. in 10 c.c. of solution, the normal St. Lawrence

River water is reduced to a rusty muddy mixture, and the dosed tail-water sample, brought to the same concentration with only about one-quarter of the relative evaporation, is much cleaner and much more easily treated. The dilute salt solution of the same concentration, of course, contains no organic matter, and is, therefore, by far the clearest and best of all the samples.

This unbalancing of the evaporations, and the differences between concentrating by evaporation and diluting with distilled water modify to such an extent the ability to detect the end points of the three classes of titration that the errors of titration are not only still present, but may even be increased by completely equating the titrations. This remark applies to the method of concentrating the normal head-water sufficiently to equate the titrations, and the difficulty, it may be remarked, is the more serious where the normal head-water contains less chemical initially.

The differences between the tests of August 7th and 17th and the tests of August 25th and September 26th to 28th have been pointed out. It is not surprising, therefore, to note that there is a very observable effect on the relative errors of the end points. Thus, in the tests where 10 c.c. of dilute salt solution have titrated to only 27 or 28 c.c., the errors are 0.165 and 0.130, respectively, though the titrations of the tests where 10 c.c. of salt solution have titrated to about 55 or 56 c.c. are only 0.084 and 0.070 c.c., respectively.

An exhaustive research for the causes of these discrepancies might be made, but it is apparent that the waters of different streams may differ, and, moreover, the waters of the same stream may differ at different times. It is therefore much better to eliminate this error by adopting the special methods which will be fully explained presently. On this account, no extended study of this particular error will be made except to compute the average correction to be applied to the titration of the normal head-water to reduce it to a value which is in error by the same percentage as that which affects the tail-water titration. Incidentally, the approximate correction to be applied to the titration of the dilute salt solution when it differs from the titration of the tail-water can be ascertained.

In order to make the determination, it is desirable to use all the reliable tests which have been made. This, however, will not include

the tests of July, as they are to be looked on as being more or less untrustworthy, notwithstanding the fact that the average corrections computed from them will not differ greatly from those computed by using the other tests. It will be possible, however, to use the dilution tests at the bottom of the table, and thus secure advantages from all the tests which may be considered as entirely trustworthy. Probabilities might be formally applied, but the following treatment will be quite sufficient, in view of the paucity of refined observations.

If we represent by c_1, c, and c_2 the average of the corresponding titrations for August 7th and 17th, and let x and y be the corrections to c_1 and c, respectively, to be applied to these quantities to reduce them to quantities having the same percentage of error as c_2, supposing that the errors are functions of the magnitudes of the quantities, we should have,

$$(c_1 + x) + (c + y) = c_2 \ldots\ldots\ldots\ldots\ldots\ldots (115)$$

In similar manner, for the tests of August 25th and September 26th to 28th, observing that the normal head-water and tail-water samples titrate substantially the same as on August 7th and 17th, we should have for the average titrations

$$(c'_1 + x) + \frac{1}{2}(c' + z) = c'_2 \ldots\ldots\ldots\ldots\ldots\ldots (116)$$

For the mean titrations of the samples A and B of dilute salt solution at the bottom of Table 4, observing that, approximately, $A = c'$ and $B = c$, and that the ratio of dilution of A to get B is 2.0036 $= r$, say, we should have

$$\frac{1}{r}(A + z) = (B + y) \ldots\ldots\ldots\ldots\ldots\ldots (117)$$

Equations (115), (116), and (117) may now be written

$$\left.\begin{aligned} x + y &= c_2 - (c_1 + c) = -0.148 \\ x + \frac{1}{2}z &= c'_2 - (c'_1 + \frac{1}{2}c') = -0.090 \\ \frac{1}{r}z - y &= B - \frac{1}{r}A = +0.040 \end{aligned}\right\} \ldots\ldots\ldots (118)$$

which are easily computed from all the tests of Table 4, excepting those of July, which have been omitted for the reasons stated.

Thus:
$$\left.\begin{aligned} c_1 &= (13.194 + 13.085) \div 2 = 13.140 \\ c &= (27.756 + 27.697) \div 2 = 27.726 \\ c_2 &= (40.785 + 40.652) \div 2 = 40.718 \\ c'_1 &= (13.073 + 12.885) \div 2 = 12.979 \\ c' &= (55.610 + 55.210) \div 2 = 55.410 \\ c'_2 &= (40.768 + 40.420) \div 2 = 40.594 \\ A &= (55.298 + 55.463) \div 2 = 55.380 \\ B &= (27.602 + 27.757) \div 2 = 27.680 \end{aligned}\right\} \quad \ldots\ldots(119)$$

Apparently, we have three equations involving three unknowns, but it is observed that r is so nearly equal to 2 that small errors of observation introduce relatively large errors in the solutions. Thus, solving,

$$\left.\begin{aligned} x &= -\ 10.148 \\ y &= +\ 10.000 \\ z &= +\ 20.116 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots(120)$$

If r is placed equal to 2 on the left of the last of Equations (118), which may be done without appreciable error, and $\frac{1}{2}z$ is eliminated from the last two equations, we obtain

$$x + y = -\ 0.130$$

as compared with

$$x + y = -\ 0.148$$

in the first equation. Thus, we have two approximate values of $x + y$, and the most probable value is the arithmetical mean or,

$$x + y = -\ 0.139.$$

By assuming, now, that $z = -\ y$, which cannot be very far from the truth, we shall have, omitting the last of Equations (118),

$$\left.\begin{aligned} x + y &= -0.139 \\ x - \tfrac{1}{2}y &= -0.090 \\ \text{therefore} \quad x &= -0.106 \\ \text{and} \quad y &= -0.033 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots(121)$$

From the last of Equations (118) may be derived

$$z = -\ y = 0.027$$

a fair average value of y thus being about — 0.03.

The most important of these values is $x = -0.106$, which may be rounded off to -0.11, so that the correction per liter for titrations of 13 or 14 c.c. will be -0.22, and this figure must be deducted from the corresponding values of the doubled titrations, where the dosed tail-water titrates to about 40 c.c. Further, when the dilute salt solution titrates to about 55 and the tail-water to 40 c.c., the correction to be added to the titration of the salt solution is about 0.03 c.c. These values, of course, apply only to silver nitrate solutions of about the same concentrations as those used on the tests just discussed, which were about 1.5622 grammes per liter in all cases. The indicator, too, must be the same in all cases. However, the corrections would be only slightly different for concentrations of about 1.45 grammes per liter, so that no great changes need be made in the latter case.

TABLE 5.—SUMMARY OF AVERAGE CORRECTIONS FOR TITRATIONS WHERE $t_2 = 40$ C.C.

(APPLICABLE TO SUCH EQUATIONS AS (12), (14), (17), (19), (46), (53), AND (99).)

$AgNO_3 = 1.5622$ Grammes per Liter.

Indicator = 50 Grammes per Liter.

Titration, in cubic centimeters.	Corrections when tail-water titrates to about 40 c.c.
13.0	− 0.11
27.5	− 0.03
40.0	0.00
55.5	+ 0.03

From Table 5 we may compile, approximately, Table 6.

TABLE 5.—SUMMARY OF AVERAGE CORRECTIONS FOR TITRATIONS WHERE $t_2 = 55$ C.C.

(APPLICABLE TO SUCH EQUATIONS AS (12), (14), (17), (19), (46), (53), AND (99).)

$AgNO_3 = 1.5622$ Grammes per Liter.

Indicator = 50 Grammes per Liter.

Titration, in cubic centimeters.	Correction, $t_2 = 55$ c.c.
13.0	− 0.14
27.5	− 0.06
40.0	− 0.03
55.5	0.00

NOTE.—These corrections apply to ½-liter samples.

44.—Comparison of Theories.—Balanced and Unbalanced Evaporations.—Having shown how to correct the net error of titration in the case of the theory involved in Equations (12), (14), (17), (19), (46), (53), (98), and (99), it will be well to study a little more closely the theory involved in Equations (27), (28), (39), (44), (45), (56), (106), (107), and (108), with the view of eliminating this error entirely

The main feature which has been added to the theory in these equations is the very evident fact that titrations of samples which are just alike in all respects are in error by the same percentage when the titrations are performed with the same silver nitrate solution in the same way.

Take, for example, Equations (110) and (111), Sections 42 and 43, where

$$Q = q\,\frac{v\,c_s\,e - k\,v_2\,c_s\,e}{v_2\,c_s\,e - v_1\,c_s\,e} \qquad \ldots\ldots\ldots\ldots\ldots\ldots (122)$$

supposing that all titrations have been reduced to the corresponding quantities of silver nitrate per liter of solution. We at once perceive that the new restriction imposes the requirement that e is not the same for any two titrations unless the two samples are exactly alike in all respects.

Thus, if t, t_1, and t_2 are the actual titrations of the sample volumes V, V_1, and V_2 which have been reduced from the original measured volumes of the samples by dilution or evaporation, and if ρ is the ratio of dilution of the salt solution and ρ_1 and ρ_2, respectively, the ratios of the volumes of original measured sample to the volumes of the residues after evaporation, which we may term "ratios of evaporation", then we may write Equation (122) as follows:

$$Q = q\,\frac{\frac{\rho\,t}{V}\,c_s\,e - k\,\frac{t_2}{\rho_2\,V_2}\,c_s\,e_2}{\frac{t_2}{\rho_2\,V_2}\,c_s\,e_2 - \frac{t_1}{\rho_1 V_1}\,c_s\,e_1} \qquad \ldots\ldots\ldots\ldots\ldots\ldots (123)$$

in which the ratio of chemical equivalents is now considered to be different for different samples unless the actual samples of volumes V, V_1, and V_2 are exactly alike in all respects.

Now, it is easy enough to impose the condition that $t = t_1 = t_2$, by simply co-ordinating the values of ρ, ρ_1, ρ_2, V, V_1, and V_2, thus

$$\left.\begin{aligned} c &= \rho \frac{t}{V} c_s e \\ c_1 &= \frac{t_1}{\rho_1 V_1} c_s e_1 \\ c_2 &= \frac{t_2}{\rho_2 V_2} c_s e_2 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (124)$$

from which, for $t = t_1 = t_2$, supposing that c, c_1, and c_2 are known,

$$\frac{c\,V}{\rho\,e} = \frac{c_1 \rho_1 V_1}{e_1} = \frac{c_2 \rho_2 V_2}{e_2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (125)$$

and, for the moment, supposing that $e = e_1 = e_2$ for equal titrations, and that S_1 and S_2 are the measured volumes which are respectively evaporated to V_1 and V_2,

$$\left.\begin{aligned} \frac{c}{c_1} &= \rho\,\rho_1 \frac{V_1}{V} = \rho \frac{S_1}{V} \\ \frac{c}{c_2} &= \rho\,\rho_2 \frac{V_2}{V} = \rho \frac{S_2}{V} \\ \frac{c_1}{c_2} &= \frac{\rho_2}{\rho_1} \frac{V_2}{V_1} = \frac{S_2}{S_1} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (126)$$

Thus, having decided on the value of ρ, the relative sizes of V, S_1, and S_2 become known, and the absolute values are known, if, in addition, the value of V is chosen. Now, as c_1 and c_2 cannot be equal, and as the actual volumes titrated must be the same, if the samples are to titrate equally and be of the same volume, we must have, for the moment, by our less restricted theory,

$$V = V_1 = V_2 \quad \ldots\ldots\ldots\ldots\ldots\ldots (127)$$

if we are to have $e = e_1 = e_2$. Therefore

$$\frac{\rho_2}{\rho_1} = \frac{c_1}{c_2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (128)$$

which shows that the samples of normal head-water and tail-water must be concentrated by evaporation by very different quantities. Thus, if $c_1 = 10$ mg. per liter and $c_2 = 40$ mg. per liter, it is clear that we

shall have to evaporate four times as much normal head-water as tail-water to have equal titrations of equal volumes.

By our restricted theory, however, the samples of head-water and tail-water will not, by such a process, be alike in all respects, and therefore we shall have to deny that equal titrations of samples of equal volumes imply that $e = e_1 = e_2$. Hence, equations of the type of (14), (17), (46), (53), (98), (99), etc., do not admit of an elimination of the net error of titration, for the reasons just made apparent, except by making an independent study of the net corrections to be applied directly to titrations similar to that which has been previously made, Tables 5 and 6, Section 43.

45.—Elimination of the Error of Titration.—The error of titration being principally due to the dissimilarity of the conditions under which the head-water blank and the dosed tail-water samples are titrated, it is clear that this source of error may be avoided by eliminating the head-water titration and substituting for it the special dilution titration, which requires the use of such equations as (27), (28), (39), (44), (45), (56), (106), (107), and (108), and the preparation in the laboratory of a special sample as nearly like the tail-water sample as possible.

In order to have the "special dilution", as it will be called, exactly like the tail-water sample, it must be made from the same salt solution which has been used in the test; and the ratio of dilution of this salt solution with normal head-water must be as nearly as possible the same as that in the test. Moreover, the evaporation of these special samples must be conducted in exactly the same manner as the evaporation of tail-water samples, and to the same extent. This can easily be done by measuring out equal quantities of each and evaporating them over a water bath to the same extent.

It has already been explained, in Section 12, that it will always be possible to have sufficiently accurate advance knowledge of the value of the actual ratio of dilution, R, in the test, to enable a special dilution to be made in the laboratory substantially like the tail-water sample. It has also been explained, Section 17, that we need not measure accurately the ratio of evaporation of samples, merely making them alike, nominally, as small differences of concentration due to small differences in evaporation will not affect the titrations perceptibly.

Hence, this procedure is equivalent to the formal statements of the equations

$$\left.\begin{aligned} \rho_2 &= \rho'_2 \\ V &= V_2 = V'_2 \\ c &= \rho \frac{t}{V} c_s e \\ c_2 &= \frac{t_2}{\rho_2 V} c_s e_2 \\ c'_2 &= \frac{t_2}{\rho_2 V} c_s e'_2 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (129)$$

It will be sufficient to discuss the nature of this procedure as it affects any one of the equations previously enumerated, for example, the first of Equations (106), Section 35, which is

$$r = \frac{r'}{1 + R' \dfrac{c_2 - c'_2}{c - k'' c_2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (130)$$

Substituting from Equations (129), and reducing somewhat,

$$r = \frac{r'}{1 + R' \dfrac{t_2 - t'_2}{\rho \rho_2 t \dfrac{e}{e_2} - k'' t_2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (131)$$

since, by our special laboratory process, e_2 and e'_2 are substantially equal.

Now,

$$T = \rho \rho_2 t \quad \ldots\ldots\ldots\ldots\ldots\ldots (132)$$

is the titration of a sample of salt solution of the same size as the measured tail-water, or special dilution, samples, as computed from the actual titration of a salt-solution sample of the same volume as the evaporated samples of tail-water or special dilution. That is, ρt is the titration of a sample of salt solution of the size of the evaporated samples, and ρ_2 is the ratio of the size of the measured sample to the size of the evaporated sample.

Thus, R' approximating R, we have,

$$r = \frac{r'}{1 + R' \dfrac{t_2 - t'_2}{T \dfrac{e}{e_2} - k'' t_2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (133)$$

in which T is the computed titration of a salt-solution sample of the same volume as that measured for the tail-water and special-dilution samples based on the titration of a dilute salt-solution sample of the same size as the nominal volume of the evaporated samples.

It may be readily seen that, when t_2 and t'_2 are nearly equal, an error in T has no appreciable effect on the value of r, and that when $t_2 = t'_2$, the result is entirely independent of T, and therefore of any error in T.

It may be observed that e and e_2 are not necessarily equal, as the sample of dilute salt solution, though of exactly the same size as the others, is different in other respects. It is a dilution with distilled water and, therefore, does not contain the same constituents as the others. This will, in a small degree, affect the end point determination; but it must be observed that the error is relatively small, under the conditions imposed, and affects only those terms of the equations which are themselves relatively small and tend to vanish altogether when the conditions of Equations (129) and (133) are approached. Therefore, it may be concluded that the special laboratory process outlined in the foregoing theory may be used to obviate the necessity for correcting titrations, as the chemical procedure involved eliminates the value of the concentration of the normal head-water from the equations, and with it the necessity of dealing directly with any of the properties of the head-water.

That the magnitude of any residual systematic error will not affect the result of a test appreciably, may be ascertained by discussions similar to those of Sections 16 and 43, where it is shown that the systematic error due to titrations of dissimilar samples in the turbine tests did not affect the results given by the method of special dilutions by perceptible quantities.

As Equations (106) and (107) express the same conditions, the error will be exactly the same in the two cases. Indeed, Equations (106) may be derived from Equations (107) by eliminating c_1 and solving for r, or R, as the case may be, although it is a solution where k'' has been inserted for a function of k', k, r', and r, which has a value nearly equal to unity. See Equation (96), Section 32.

Independently of Equations (106), it may be shown that an error in c tends to be eliminated in Equations (107). Suppose, for example,

that c becomes $c + \delta$ by reason of the error, δ. Then the resulting error in c_1 is

$$\frac{R' c_2 - (c + \delta)}{r'} - \frac{R' c_2 - c}{r'} = -\frac{\delta}{r'} \quad \ldots\ldots (134)$$

and the corresponding error in r is

$$\frac{(c + \delta) - k c_2}{c_2 - \left(c_1 - \frac{\delta}{r'}\right)} - \frac{c - k c_2}{c_2 - c_1} \quad \ldots\ldots (135)$$

which reduces to

$$\frac{\delta - \frac{\delta}{r'} \frac{c - k c_2}{c_2 - c_1}}{(c_2 - c_1) + \frac{\delta}{r'}} \quad \ldots\ldots (136)$$

When r and r', however, are closely equal, as is the case supposed in the use of Equations (107), we must have, closely,

$$r' = \frac{c - k c_2}{c_2 - c_1} \quad \ldots\ldots (137)$$

so that the error in r, expressed by Equation (136), tends to vanish when r and r' are closely equal.

46.—Errors Considered Separately.—Error 1.—Initial Content of Chemical.—It is clear that in eliminating c_1 by Equations (107), or similar equations, as mentioned in Section 37, and the special dilutions, the properties of the normal head-water are eliminated. This is the first source of error enumerated in Section 41. Equations (27), (28), (39), (44), (45), (56), (106), (107), and (108), result from the elimination according to the methods to be used in the test. By using any of these equations in connection with special dilutions, the error resulting from this source will be entirely eliminated, and, along with it, the necessity for titrating the blank sample of head-water. Indeed, it is possible to eliminate this error even where the initial content is variable, as will appear in the next section. In order to gain some idea of the nature of the normal head-water, as regards initial content of chemical, a study of Table 7, giving the values, in cubic centimeters, of silver nitrate during the entire series of tests, will be enlightening.

It will be observed from the figures in Table 7 that the content of chlorine in the St. Lawrence River was almost, if not quite, constant during the tests. The increase of the titration from about 26

c.c. of silver nitrate to 28 c.c. near the close of the tests is due to a change in the strength of the nitrate from a concentration of 1.5622 grammes per liter to 1.45 grammes dissolved in 1 liter of distilled water, which would correspond to a concentration of about 1.449 grammes per liter.

TABLE 7.—INITIAL CONTENT OF CHLORINE IN NORMAL HEAD-WATER DURING THE TURBINE TESTS, EXPRESSED IN HUNDREDTHS OF CUBIC CENTIMETERS OF SILVER NITRATE SOLUTION PER LITER OF SAMPLE, WHEN THE TITRATION IS OF ½ LITER EVAPORATED TO 10 C.C. IN A CASSEROLE OF ABOUT 11 CM. DIAMETER. THE STRENGTH OF THE SILVER NITRATE WAS APPROXIMATELY 1.56 GRAMMES PER LITER IN ALL THE TESTS EXCEPT IN THE SECOND SERIES ON UNIT NO. 11 WHEN IT WAS ABOUT 1.45 GRAMMES PER LITER. THE STRENGTH OF THE CHROMATE OF POTASSIUM INDICATOR WAS ABOUT 50 GRAMMES PER LITER IN ALL CASES, AND THE QUANTITY INTRODUCED INTO THE SAMPLE WAS FROM TWO TO THREE DROPS BY A "TK" DROPPING BOTTLE. THE GENERAL RULES FOR THE TITRATIONS ARE GIVEN IN SECTIONS 88 AND 89. THE FIGURES ARE CORRECTED TO AGREE WITH THE SECOND PART OF THIS TABLE, SEE SECTION 43, TABLES 5 AND 6.

(NOTE: A small error in titration makes a relatively large error in the tabulated values herein.)

Thus the tests on Unit No. 11 in September—Nos. 105-109—average 25.92, and those in November—Nos. 111-122—average 27.98. In the former case the concentration of the nitrate was 1.5622; in the latter case it was about 1.449. Hence the titration in November, computed from that in September, should be

$$25.92 \times \frac{1.5622}{1.449} = 27.95$$

which agrees very well indeed with the average for November mentioned previously.

The concentration of nitrate in November was taken at about 1.45 grammes per liter so as to facilitate the determination of the approximate salt content of the normal head-water from the titration of a sample by simply dividing by 2. Concentrations computed in this

way, however, are subject to the error of titration. This error, for normal head-water, is in the neighborhood of 1% on the side of excess.

47.—Error 2.—Variability of Initial Content.—Whether the elimination of the error due to initial content is complete or only partial depends in large measure on whether this content is variable and on the method of taking samples.

In order to eliminate the error due to variability of content, it is necessary only to secure an average sample. Such an average must be a volume average and not a time average. However, as the velocity at any point in the cross-section at the head-water sampling station is nearly constant, a continuous sample taken at a uniform rate during any test, or part of a test, will represent a fair average for that point during the observation. If the variability is so great as to cause very different concentrations in different parts of the section at the same time, more than one sample will be required for the normal head-water. If, in addition, there is much variation in velocity from point to point of the cross-section, the concentrations of the samples from these points would have to be weighted in proportion to the relative velocities at the same points.

Fortunately, the latter precaution is seldom needed; a single head-water pump, operating continuously during a test, will suffice in the majority of cases. Indeed, the constancy of salt content can be checked by taking several continuous samples from each pump during a test, and noting that the special dilutions resulting from these samples all titrate substantially alike.

Table 7, Section 46, gives a list of normal head-water titrations observed during the tests.

48.—Error 3.—Variability of Standard Chemical.—If the concentration of the silver nitrate should vary during a series of titrations, it may introduce an error of any magnitude, depending on the extent and character of the variations. At first sight, it would appear that this error cannot be eliminated; but, on closer study, it will be apparent that if the methods advocated in this paper are followed, gradual changes may be eliminated by group titrations. Suppose, for example, that two chemists are each titrating the same test in two independent treatments. It will not matter if their silver nitrate solutions are different; they should arrive at the same result, notwithstanding, for titrations vary in magnitude in an inverse manner

with variations of concentration, being nearly in an inverse ratio thereto, and, as the methods advocated herein require that all titrations shall be approximately equal, they will be affected in any test by the same constant error, which, therefore, will cancel from the equations, because only the ratios of the titrations enter such equations.

If, therefore, the same number of duplicate samples of each solution are prepared, the samples may be titrated in groups containing one or more samples of each solution. Only one chemist should titrate any one group, and, during its titration, he should be sure to use the same instruments, the same silver nitrate solution, and the same indicator solution. He should even go so far as to approximate the same readings of his burette and other scales, in measuring his solutions. In fact, the burette should be filled nearly, if not exactly, to the zero of its scale before each titration, and should be proportioned to the work so that it will be almost emptied by each titration, with only a good practical margin to spare. This is on the side of accuracy and economy. The reason for this is more apparent when it is observed that, by following these directions, each titration of any group will be affected with the same constant error, including the personal error of the chemist, as only one chemist is permitted to titrate any one group of samples.

Not only should the samples be thus divided into groups, but each group must contain nearly the same number of samples of each kind, so that they may be titrated one kind after the other as rapidly as possible, with perhaps an extra sample of one kind, so that the titration of the group may begin and end with that same kind of sample.

For example, suppose a test has been run in which there are twelve tail-water samples, T_1, T_2, etc., four special dilutions, D_1, D_2, etc., and four salt solution samples, S_1, S_2, etc. Then, to eliminate the errors due to changes in the nitrate, the personal error of the chemist, and errors of the graduation marks on the burette, the preceding directions must be followed, and the groups may be arranged as follows:

GROUP TITRATIONS.

Group 1.....	T_1	D_1	T_2	S_1	T_3
Group 2.....	T_4	D_2	T_5	S_2	T_6
Group 3.....	T_7	D_3	T_8	S_3	T_9
Group 4.....	T_{10}	D_4	T_{11}	S_4	T_{12}

A Second Grouping.

$$\begin{array}{ccccc} T_1 & D_1 & T_2 & S_1 & T_3 \\ T_4 & S_2 & T_5 & D_2 & T_6 \\ T_7 & D_3 & T_8 & S_3 & T_9 \\ T_{10} & S_4 & T_{11} & D_4 & T_{12} \end{array}$$

There appears to be no urgent need for the second grouping, rather than the first, though some chemists may prefer it.

The second grouping might cause confusion in entering the record on the record sheets, with the possibility of making an error by entering a special dilution in a salt-solution space. This error, however, would be small if the directions are followed closely, as all titrations of the same group are nearly equal among themselves.

Each group should be titrated as rapidly as possible, by the same chemist, as previously explained, and in the order of reading from left to right, or the contrary. As a consequence of this procedure, it will be seen that gradual changes in the chemicals used, such as increasing concentration due to evaporation or changes in temperature, will not affect the results if the work is executed as outlined.

49.—Errors 4 and 5.—Indicator, and Excess of Standard.—The determination of the end point of any reaction is always affected by an error. Part of this error may be due to reactions between the indicator and standard solutions used and part may be due to the necessity of having an excess of standard in order to make distinct the indication of the end point. In either case, the titration, as determining the quantity of chlorine, or other chemical, is in error.

So far as determining the quantity of water, or other liquid, is concerned, however, it will not be in error if the method of special dilutions developed in the tests described herein is used. For such an excess of titration will affect all the titrations alike, as they are of nearly the same magnitude for substantially equal samples.

Indeed, it follows as a consequence of the methods laid down that constant errors of titration are such only as relate to the exact determination of the quantity of chemicals present. They are not errors at all as relates to the determination of volumes of liquids by the method of special dilutions.

50.—Error 6.—Uniformity of Mixture and Distribution of Salt in Tail-Water.—It seems that many engineers have an idea that failure to secure uniformity of mixture means failure to secure an

accurate test. That such is not the case may be readily seen from the following and similar considerations.

In the tests described there were two draft-tubes delivering the discharge from a pair of vertical twin runners. In some of the tests the distribution of salt between the upper and lower draft-tubes was nearly equal; in other cases there was as much as 15% and even 20% more in one draft-tube than in the other, as may be seen by examining the titrations of the tail-water samples which are collected in Part IV. Let it be required to determine the possible errors due to this cause:

It is clear that it is a volume average of concentration which is required for the value of c_2 in the equations. Therefore, if the concentration varies from point to point in the cross-section of the tail-race, the arithmetical mean of the concentrations of several samples taken at these points will not be an average concentration unless the velocity is uniform at all points, which is never the case. It is necessary, therefore, to determine the weighted mean, the weight of any concentration being the ratio of the quantity of water discharged at that concentration to the total quantity discharged during the test. Thus, if W_1 is the volume of water discharged by the upper draft-tube at the average concentration, c_1, and W_2 is that discharged by the lower draft-tube at the average concentration, c_2, then the weighted mean, or volume-average of the concentration for the test, will be

$$M = c_1 - \frac{W_2}{Q}(c_1 - c_2) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (138)$$

where Q is the total discharge of both draft-tubes during the test.

Take, now, the most unfavorable case, where the concentrations in the upper and lower draft-tubes are, respectively, 55 and 45 c.c. of silver nitrate. Further, suppose that the upper draft-tube discharges 20% more water than the lower one. This, of course, is a far greater difference than can reasonably be imagined, as the runners are exactly alike. However, with this excessively unfavorable assumption, observing that the discrepancy between the discharges is about 10% of the total discharge, we have,

$$M = 55 - \frac{50}{110}(55 - 45) = 50.45$$

as against

$$\frac{55 + 45}{2} = 50$$

for the arithmetical mean. Thus, the error introduced is less than 1% under assumptions which must be more unfavorable by far than the actual conditions under which the test was executed. It would be much more like the actual conditions to assume that the upper runner differed from the lower by only about 5%, in which case the weighted mean would be

$$M = 55 - \frac{50}{102.5} \times 10 = 50.12$$

which does not differ from the arithmetical mean by as much as ¼ of 1 per cent. This is probably too large an error, as the gates of the two water-wheels are undoubtedly set so as to cause a nearer approach to equality of discharge than that last supposed.

It follows, from the preceding comparisons of the arithmetical and weighted means, that, if we have anything approaching the true weights of the concentrations observed in the tail-race, we can compute an average concentration which will differ from the true average by an error which is measured by only a few hundredths of 1%, and this, too, where there are considerable variations among the observed concentrations and velocities.

The foregoing remarks apply particularly to the case of two draft-tubes. In the case of a single draft-tube, or tail-race, there are likely to be greater variations of relative velocity from point to point than has been supposed to exist between the two draft-tubes. Thus, this case requires a study of the errors similar to that for the case of a pair of draft-tubes, but it will usually be found that the distribution of salt over the section of a single draft-tube is so much better than it is between two draft-tubes that the resulting error is even less than those just discussed.

Take, for example, one of the best tests on Unit No. 13, such as Test 41. The detailed distribution of concentration in the draft-tubes is shown by Table 8.

TABLE 8.—*Distribution of Concentration in Test 41, as Shown by the Titration of the Eighteen Tail-Race Samples.

	West Half.			East Half.		
Upper draft-tube	53.20	54.45	53.92	53.85	54.40	54.94
	53.45		54.70		54.85	
Lower draft-tube	54.05	53.85	53.80	54.05	54.30	53.25
		53.90		54.20		54.55

*The units are cubic centimeters of silver nitrate consumed in titration.

It will be seen at once that the lowest concentration is 53.20, and the highest is 54.94, or a maximum variation among samples of only a trifle more than 3% of the average. It follows that the arithmetical mean, 54.095, is certainly within 1½% of the truth, and the probable error is only a small fraction of 1%, the assumption being that the average distribution of chlorine among the various samples is uniform, and that the figures of Table 8 vary by accidental errors due to one cause or another.

If, on the other hand, it is considered that the variations in Table 8 are real variations of concentration, then we must seek to weight each concentration by the relative velocity at the point where it is observed. It will be better engineering, however, and far more economical of time, where a number of tests are to be thus discussed, to divide the upper and lower draft-tubes into east and west halves, thereby dividing the tail-race into quarters, and then to weight the mean concentration of each quarter with the mean relative velocity of that quarter. It may be remarked, also, that we are now regarding the tail-race as the single discharge passage from a turbine unit. This is reasonable, as the concentrations are so nearly uniform that there is no material variation of the mean concentrations between the upper and lower halves of the tail-race. Of course, attention might be confined to either upper or lower draft-tube, if one wished to be very consistent. The result will be the same in either case.

The mean concentrations of the four quarters may then be arranged as follows:

COMPARISON BY QUARTERS.

53.944	54.510
53.900	54.070

By thus taking means for the quarters, the maximum variation among the four averages for the samples of each quarter has been diminished to 0.61 c.c., or only a trifle more than 1%, as compared with 3% when the samples are taken separately. It may well be concluded, then, that the arithmetical mean of all samples is well within ½ of 1% of the truth, at least in this particular case, and, consequently, that the weighted mean will be within a small fraction of 1% of the truth.

It will also be of interest to compare the upper and lower and east and west halves of the tail-race concentrations, thus:

COMPARISON BY HALVES.

Mean of nine samples, upper half	54.196
lower half	53.994
Mean of nine samples, west half	53.922
east half	54.290

These results show that the variation of average samples has again been reduced, and we note that the variation for the upper and lower halves is only 0.2 c.c., and it is less than 0.4 c.c. for the east and west halves. Owing to this narrowing of the variation, it is apparent that the probability is very high, in this particular case, that the arithmetical mean is not in error by more than $\frac{1}{4}$ of 1% at most, and a mean derived from anything like the true weights cannot be in error by as much as $\frac{1}{10}$ of 1 per cent. All this may be proved, with large margins in favor of the less formal conclusions, by a simple application of the principles of probability, but would not add anything to the probability of the fact which we show, namely: that the variability of concentration is not such a serious matter as many have supposed, and, above all, that it is quite possible, in testing large-capacity turbines operating on low heads, to secure remarkably uniform distributions, even where there are two water-wheels operating on one shaft and discharging through two separate draft-tubes.

By referring to Fig. 37 the proper weights for the concentrations of the four quarters may be shown to be about as follows:

	West.	East.	Mean.
Upper	0.30	0.20	0.50
Lower	0.33	0.17	0.50

Therefore, the weighted mean for this test may be computed very closely as follows:

$$0.30 \times 53.944 = 16.183$$
$$0.33 \times 53.900 = 17.787$$
$$0.20 \times 54.510 = 10.902$$
$$0.17 \times 54.070 = 9.192$$

Weighted mean.. 54.064

A comparison of the weighted and arithmetical means may be made, thus:

Arithmetical mean	= 54.095
Weighted mean	= 54.064

which are seen to differ by less than $\frac{6}{100}$ of 1%, with the probability that the weighted mean is in error by even less than this, as it has been repeatedly shown in the chemical laboratory that the means from sets of six or eight equal samples will titrate within $\frac{5}{100}$ of 1% of each other.

This latter, of course, is an accidental error as distinguished from the systematic error due to erroneous weighting which has just been discussed. This distinction must be carefully made in criticising accurately made tests; and the residual error, resulting from these two classes, must be shown not to be greater than a certain quantity before any conclusions can be drawn as to the accuracy of the tests.

By analyzing the salt distribution in the tail-race in a manner similar to the foregoing, a close estimate of the degree of accuracy attained in the weighted mean for the tail-race concentration in any particular test can be made, and thus the effect on the final result of the test may be ascertained. It is readily seen, therefore, that, so far as mixture and distribution of salt are concerned, the best tests are well within the desired degree of accuracy of $\frac{1}{10}$ of 1 per cent.

Of course, it is assumed, in making this last statement, that the weights are not vastly incorrect, although there is a very wide margin of error permissible. For example, by taking the weights twice as great, relatively, on the west side of the race, as they are in the foregoing table of weights, we would have:

	West.	East.	Half Tube.
Upper.....	0.375	0.125	0.50
Lower.....	0.400	0.100	0.50

which leads to the following calculation of the weighted mean, on the assumption that the weights used in the computation of the mean of 54.064, above, are only half as great relatively on the west side as they should be:

$$0.375 \times 53.944 = 20.229$$
$$0.400 \times 53.900 = 21.560$$
$$0.125 \times 54.510 = 6.814$$
$$0.100 \times 54.070 = 5.407$$

Weighted mean, based on assumed weights..... 54.010

Thus, if the weights used in obtaining the mean, 54.064, are only half as large on the west as they should be, there would be introduced an error in the weighted mean of only 0.1 of 1 per cent.

Now, Fig. 37 is based on current-meter observations in the tail-races of the units tested, and, though the current-meter work is to be regarded as only a rough field operation, without correcting the meters for errors due to turbulence, it is difficult to suppose that the errors in the relative velocities, east and west, can be more than 15 or 20 per cent. Hence, it is concluded that no serious error results in the best tests by reason of errors in weighting the concentrations of salt in the tail-race samples.

Finally, it may be stated that the ultimate determination of the efficiencies of the units justifies the last conclusions, not only when tests of the same unit are compared with one another, but also when the tests of Units Nos. 12 and 13 are compared. These two units being exactly alike, their efficiencies should be equal, with only such differences as may be due to slight differences in hydraulic conditions, adjustment, packing, lubrication, etc.

51.—Distributing Pipes and Centrifugal Pump.—As explained in the description of the testing plant, Part III, the salt solution was injected into the suction of an 8-in. centrifugal pump, which discharged into a header feeding twelve 2-in. pipes. Six of these 2-in. pipes passed down the stop-log slot on the west and six on the east side of the head-race. These pipes are numbered from 1 to 12, the odd numbers being west, the even numbers east, and progressing downward.

There were six horizontal 2-in. pipes extending across the head-race, each perforated with three series of holes, one series along the top element discharging vertically upward, one series along the bottom element discharging downward, and the third series along the up-stream element discharging against the current. A pair of differential pulleys—one such pulley being at each side of the head-race—facilitated the adjustment of these six horizontal distributing, or sprinkling, pipes, so that they divided the rectangular cross-section of the race into six equal horizontal strips, with a pipe in the horizontal median of each strip.

The twelve distributing pipes from the header were connected by 2-in. hose to the ends of the risers leading to the horizontal sprinkling pipes in pairs, so that Nos. 1 and 2 supplied the upper, or No. 1, sprinkler, with salt solution; Nos. 3 and 4 supplied the next lower, or No. 2, sprinkler, and so on downward.

In the tests on Unit No. 13 these horizontal sprinklers were open throughout their length, but in some of the later tests a block of wood, or plug, was introduced at the middle of the pipe in the center line of the head-race.

The relative discharge from each of the various parts of the distributing system was controlled by gate-valves and gauges connected to the distributing pipes, 4 or 5 ft. below the point where they branched from the header. At these points there was also provided a pet-cock on each pipe, so that samples of the mixtures being pumped into the different pipes could be secured.

During the course of a number of the regular tests, samples were taken from these cocks and titrated so as to obtain an estimate of the relative quantities of salt passing through each of the twelve pipes leading from the header.

In this way it was proved conclusively that the method of introducing the salt into the centrifugal pump effected a perfect mixture with the water being raised from the canal by the pump, so that the discharge was a salt solution of perfectly uniform strength in all the pipes at any given time. The experiments also enable one to calculate the discharge of the centrifugal pump, although no effort was made to observe the power consumed by the pump or to compute its efficiency.

The observed titrations, uncorrected for temperature effects and calibrations of glassware, for two such tests as have been described, are given in Tables 9 and 10, with approximate calculations for the

TABLE 9.—SHOWING UNIFORMITY OF MIXTURE DISCHARGED FROM THE 8-INCH CENTRIFUGAL PUMP IN TEST *V*, UNIT NO. 13, AUGUST 10TH, 1914.

The figures are in cubic centimeters of silver nitrate consumed in titration up to the end point.

Horizontal pipe No.	West.	East.
1	25.75	26.15
2	25.95	25.85
3	25.85	25.80
4	25.85	25.95
5	25.75	25.75
6	25.80	25.70
Means	25.825	25.867
Average of all		25.846
Average, less 0.07 c.c., by Table 5, Section 43		25.78

discharge of the pump in all the tests where distributing-pipe samples were taken. The practical equality of the titrations of the twelve samples taken from the distributing pipes is very evident.

The value of v_2 for these twelve titrations, therefore, is about 25.78. A sample consisted of 10 c.c. pipetted from a stock solution made up by taking 20 c.c. of the discharge from a given pipe and diluting to 500 c.c. with distilled water. Thus, by multiplying the observed titration by $100 \times 25 = 2\,500$, there results a number which is, theoretically, what the titration of 1 liter of the actual discharge would have been. The uncorrected concentration of the salt solution is 544 900 and the concentration of the normal head-water, as usual, is about 25.72. Therefore, the calculation of the discharge of the pump for Test *V*, with considerable approximation, is

$$v = 544\,900$$
$$v_1 = 25.72$$
$$v_2 = 2\,500 \times 25.78 = 64\,450$$
$$q = 0.24 \text{ (from the record)},$$

and

$$Q = 0.24\ \frac{544\,900}{64\,450} = 8.46 \times 0.243 = 2.06 \text{ cu. ft. per sec.}$$
$$= 2.06 \times 60 \times 7\tfrac{1}{2} = 928 \text{ gal. per min.}$$

The elevation of the surface of the canal water was 198.6, and that of the center of the pump was about 217, so that the suction lift was 18.4 ft. The speed of the pump was about 600 rev. per min.

TABLE 10.—MIXTURE DISCHARGED FROM 8-INCH CENTRIFUGAL PUMP IN TEST 26, UNIT NO. 13, AUGUST 26TH, 1914.

Horizontal pipe No.	West.	East.
1	28.09	28.12
2	28.15	28.07
3	28.13	28.15
4	28.10	28.07
5	28.10	28.10
6	28.20	28.25
Means	28.128	28.127

Average of all.....28.13
Average, less 0.06 c.c. by Table 5, Section 43.....28.07

Computation with approximate data from test:

$v = 528\,600$

$v_1 = 25.72$

$v_2 = 2\,500 \times 28.07 = 70\,180$

$q = 0.24$ (from record),

$$Q = 0.24 \frac{528\,600}{70\,180} = 0.242 \times 7.54 = 1.82 \text{ cu. ft. per sec.}$$

$$= 1.82 \times 60 \times 7.5 = 820 \text{ gal. per min.}$$

Elevation of surface of canal water = 195.8

Suction lift = 217 — 195.8 = 21.2 ft.

Thus the effect of the additional suction lift is apparent in the decreased discharge, the pump running at about the same speed as before.

Table 11 gives a summary of all the titration tests of the discharge of the centrifugal pump, with foot-notes explaining certain apparently anomalous results due to varying conditions of operation.

NOTE.—The effect of a change in suction lift is very apparent in these tests. The readings of gauges on distributing pipes can be found in Tables 46, 47, 48, and 49. No exact pressures are available. See Section 101.

* The discharge of this pump should be added to the turbine discharge determined by the current meters in tests where the pump was running, as the pump discharge was shunted around the meter section.

† Although the data are uncorrected for effects of temperature, they are sufficiently accurate for the purpose of this table.

‡ Test 118 was on Unit No. 11. All the other tests of this table were on Unit No. 13. Unit No. 13 was equipped with a direct-current generator, but No. 11 was equipped for alternating current.

§ In Test *S*, all six of the feeders to sprinkling pipes on west side of head-race shut down, which accounts for the low discharge of pump in this test.

‖ In Test 118 another motor was used, which ran the pump at speeds considerably greater than 725 rev. per min. Two of the sprinklers, however, were shut down.

The principal information to be gained from these tests is that a centrifugal pump appears to be an excellent mixer, and, consequently, is especially susceptible to the chemical method of turbine testing. The pump was an old one, and the runner was in poor condition, so that the efficiency was undoubtedly low. Neither was the speed anywhere near high enough in most of the tests, all of which facts, undoubtedly, added to the mixing qualities of the pump.

52.—Distribution Tests.—It was shown in Section 51 that the distribution of salt among the twelve distributing pipes was uniform. The results of several tests on Unit No. 13 to determine the distribution of salt in the tail-race arising from the separate discharge of each sprinkling pipe and also the results of tests to ascertain the time required after starting a test to establish steady conditions of distribution in the cross-section of the tail-race will be discussed in this section.

The former of these matters was the subject of investigation in Test *M*, July 25th, 1914. The salt-solution tank was filled with a strong solution, the usual samples of which titrated as follows:

SALT SOLUTION, TEST *M*.

54.80	54.85
54.75	54.75
54.80	54.80
54.80	54.80
219.15	219.20
Mean..... 54.79	

After this each of the six sprinkling pipes was opened in succession for about 5 min., but with scarcely sufficient time intervening to permit the establishment of steady conditions in the pipes and tail-race. The sample bottles at the tail-race sampling pumps were changed each time so that separate sets of samples were obtained for each pipe. There were thus obtained 84 tail-race samples, 14 representing the relative distribution of salt in the tail-race for each of the six sprinklers.

The numbers of the pipes progress downward, so that Pipe 1 was the uppermost and Pipe 6 the lowest in the head-race distributing system. The tail-race sample pipes were in the cross-section at the stop-log slot of Unit No. 13, just outside the power-house. Some time

afterward this section was abandoned on account of the difficulty of keeping the ¼-in. pipes in repair.

TABLE 12.—TESTS *M*.—DISTRIBUTION OF SALT IN TAIL-RACE. TITRATIONS OF THE INDIVIDUAL TAIL-RACE SAMPLES.

NOTE.—The figures below the twelve regular samples represent, respectively, the relative concentrations at the center lines of the upper and lower draft-tubes, and were determined from samples taken from Pumps 41 and 42.

Table 12 shows the actual titrations of samples in the tests. These should be reduced by 13.5 c.c., that is, by 135 tenths, the titration of ½ liter of normal head-water, in order to secure numbers representing the relative salt content of the tail-water at the various sampling pipes resulting from the introduction of salt solution through the particular sprinkling pipe which is open in any particular test. It will make the different tests more directly comparable with each other, however, to reduce these resulting relative concentrations to percentages of the mean concentration for the whole tail-race by dividing each by this mean. The result of this compilation is given in Table 13, which, therefore, represents quite accurately the relative distribution of concentration in the tail-race due to each of the six sprinkling pipes.

From Table 13 it is apparent that Pipes 1 and 2 deliver nearly all their salt supply to the upper draft-tube, and Pipes 5 and 6 supply principally the lower draft-tube. Pipes 3 and 4 divide their supplies much more evenly, but Pipe 3, being above the middle of the cross-section in the head-race, naturally supplies a greater proportion to the upper draft-tube, and Pipe 4, being below the middle supplies a

greater proportion to the lower draft-tube. All this might easily have been anticipated, but Table 13 is very valuable, as it enables one to secure a uniform distribution in the tail-race by adjusting the valve on the proper pipe in the head-race. It was by using this table that good distributions were secured in the tests.

TABLE 13.—TESTS *M*.—SEPARATE DISTRIBUTIONS OF SALT IN TAIL-RACE OF UNIT NO. 13 DUE TO EACH OF THE SIX SPRINKLING PIPES IN THE HEAD-RACE BASED ON TWELVE SAMPLES OF TAIL-WATER.

(The figures represent percentages of the mean values of the concentrations at the twelve sampling pipes.)

Table 12 gives additional evidence in favor of the conclusions of Section 50, that variations of distribution are not vitally important where the water in the tail-race is all flowing outward, that is, out of the tail-race. This is made clear by Table 14, a compilation of the average values of that part of the tail-race concentration in Tests *M* which is due to the separate sprinkling pipes. Thus, there were six tests compared in Table 12; taking the arithmetical average in each

TABLE 14.

Number of sprinkling pipe open.	Salt rate, in liters per second.	Average equivalent titration, in tenths of cubic centimeters.	Ratio of titration to salt rate.
1	1.53	93	61
2	1.63	87	53
3	1.62	97	60
4	1.61	90½	57
5	1.71	84½	49
6	1.78	90	50
Means	1.65	90.3	55

case and deducting 13.5 c.c., that is, 135 tenths, Table 14—a table of averages—has been compiled.

The salt rate is simply the rate of discharge of the salt solution during the times the samples were being taken in the various tests (about 5 min. in each test). The strength of the salt solution is stated in tabular form at the beginning of the section. A close agreement between the salt rate and the mean concentration in the tail-race need not be expected, nor required, in these tests, as the period of the tests was too short for such a degree of accuracy, and it is doubtful whether sufficient time was allowed between tests. Moreover, it does not appear that the salt rate was maintained anywhere near constant during any test, so that it is easy enough to account for these variations among the mean concentrations and the ratios between them and their corresponding salt rates. These facts do not detract in the least from the importance of the conclusion which may be drawn from the fact that the average equivalent titration per liter of salt rate varies by only 10 or 12% from the mean, 55, as a consequence of opening successively the six sprinkling pipes in the head-race, thereby varying the relative intensities of concentration in the various parts of the tail-race due to the introduction of salt solution from nothing to more than 2½ times the mean concentration during the test, as shown in Table 13. The conclusion is the same as that of Section 50, namely, that large variations in the concentration of salt in the tail-race make relatively small variations in the average concentration computed therefrom, even though there are considerable variations of velocity in the tail-race, as in the regular turbine tests where the velocity variations were from 1 or 2 ft. per sec. on one side to 4 or 5 ft. on the other.

The ratios above computed are somewhat improved, especially for all tests after the first, which latter took place just after opening the salt valve, by weighting the concentrations according to the scheme of weights given in the diagram, Fig. 37.

Thus, the weights from that diagram for the four halves of the two draft-tubes for Test *M*, in which the gate was set at 14.5, are

Upper west	0.302	Upper tube....0.50
Upper east	0.198	
Lower west	0.320	Lower tube....0.50
Lower east	0.180	

Possibly the discharge of the upper draft-tube should have slightly more weight than the lower one, as it is supposed that the gate of the upper turbine was slightly more open than that of the lower, but the diagram is based on equal weights.

Weighting the averages for each of the four quarters of the tail-race, accordingly, Table 15 has been compiled.

TABLE 15.—TESTS *M*.—WEIGHTED MEAN TITRATIONS OF HALF-LITER TAIL-RACE SAMPLES, PER LITER PER SECOND, OF SALT SOLUTION DISCHARGED FROM EACH OF THE SIX SPRINKLER PIPES IN THE HEAD-RACE, AND RATIO OF THE WEIGHTED MEAN TO THE ARITHMETICAL MEAN.

(Compiled from Tables 12 and 13.)

(The units are cubic centimeters of silver nitrate per liter per second of salt solution for half-liter tail-water samples.)

Number of sprinkler open.	Salt-rate, in liters per second.	Weighted mean, per liter per second, of salt solution.	Arithmetical mean, per liter per second, of salt solution.	Ratio of weighted to arithmetical means.
1	1.53	6.28	6.08	1.03
2	1.63	5.34	5.34	1.00
3	1.62	5.80	5.99	0.97
4	1.61	5.47	5.62	0.97
5	1.71	4.97	4.93	1.01
6	1.78	5.05	5.05	1.00
Average of all six		5.48	5.51	
Average of last five		5.33	5.39	

The last column might be computed by weighting the ratios given in Table 13, instead of taking the quotients of the weighted and arithmetical means directly as in Table 15.

It is seen from Table 15 that 1.03, the ratio for the first of Tests *M*, is not in the direction of improving the weighted mean for this test, and that the last ratio should be greater than, instead of equal to, unity. Otherwise, all the other ratios of the last column tend to reduce the variations among the weighted means, decreasing the arithmetical means which are larger than the average and increasing those which are smaller. For example, the maximum variation of the weighted mean is $5.80 - 4.97 = 0.83$, and that of the arithmetical mean is $5.99 - 4.93 = 1.06$. Had the tests been of longer duration,

this result would have been materially improved, and the variations among the values of the weighted mean would have tended to vanish altogether with increasing care in the experiments. Of course, we depend here, also, on the current-meter tests, on which Fig. 37 is based. There are no doubt errors of some magnitude in the current-meter work, but the error introduced into the weights has been shown not to be serious for the purpose of computing the discharge.

TABLE 16.—OBSERVED AND WEIGHTED CONCENTRATIONS OF SALT IN TAIL-RACE DUE TO THE SEPARATE DISCHARGE FROM EACH QUARTER OF THE HEAD-RACE SPRINKLING SYSTEM, TESTS 101-104, UNIT No. 11.

(The unit is the titration of 100 c.c. unevaporated tail-water. $AgNO_3 = 1.56$ grammes per liter.)

	Means...	9.18		8.70	
103 Lower east quarter open	Upper...	2.71	3.19	1.05	0.86
	Lower...	13.32	12.25	5.02	1.51
	Means...	7.87		7.94	
104 Upper east quarter open	Upper...	11.79	10.15	4.57	1.15
	Lower...	2.53	2.68	0.95	0.33
	Means...	6.79		7.00	

Several tests similar to those just discussed were made on Unit No. 11. These are Tests 101-104. In each case the sprinkler pipes of only one-quarter of the head-race were opened, the pipes in the other three-quarters remaining closed. The effect on the distribution is shown in Table 16.

In this case only 100 c.c. of tail-water constituted a sample, and this was titrated directly without evaporation. Thus, the titrations of these tests and those of Tests *M* are not directly comparable, the titrations of 100 c.c., unevaporated, being relatively considerably larger than those for 500 c.c. evaporated. Moreover, the titration of 100 c.c. of normal head-water directly requires from 3.50 to 4.50 c.c., which is relatively much larger than for 100 c.c. of tail-water, the comparable value probably being 3.50, which is adopted for the following discussion. This value has also been taken high on account of the fact that a 100-c.c. sample of tail-water will titrate several per cent. higher, relatively, than the half-liter samples of Tests *M*. By thus having the normal head-water titration too high, the remainder, after subtraction, will be decreased several per cent., which will tend to counteract the over-titration.

The weights for the four quarters of the tail-race for Tests 101-104 on Unit No. 11, from Fig. 39, are:

	West.	East.
Upper	0.387	0.113
Lower	0.377	0.123

When these weights are applied to the actual titrations of Table 16, the corresponding weighted titrations result.

By dividing these titrations by the salt rate and multiplying by 5 to reduce the titration to ½ liter, we should be able to make some comparison between the distribution tests on Unit No. 13, summarized in Table 15, and those on Unit No. 11. Thus Table 17 has been compiled.

These rates of titration are considerably larger than those of Tests *M*. This is due to the fact that the discharge was considerably larger in Tests *M* than in Tests 101-104. The titrations should also be proportional to the strength of the salt solution. The salt solution was not titrated, but 100 c.c. of the tail-water was titrated to about 11.8 c.c., unreduced by the initial salt content, which corresponds to

59 c.c. per ½ liter. The hydrometer readings for the salt solution in Test 105 was 1 180, and for Tests 101-104 it was 1 178, so that the salt solution was of the same strength as in Test 105 when the titration was at an average of 53.5. The titration of the salt solution in Tests *M* was 54.8, so that, admitting errors of 2 or 3%, the two tests will be comparable when the difference of discharge is taken into account. The discharges in the two cases are about as follows:

Tests *M* 1 730 cu. ft. per sec. = 49 000 liters per sec.
Tests 101—104 1 510 " " " " = 42 700 " " "

TABLE 17.—TESTS 101-104.—WEIGHTED MEAN TITRATIONS PER LITER PER SECOND OF SALT SOLUTION DISCHARGED FROM EACH QUARTER OF THE SPRINKLER SYSTEM IN HEAD-RACE OF UNIT NO. 11 FOR 100-C.C. SAMPLES OF TAIL-WATER, AND RATIO OF THE WEIGHTED MEAN TO THE ARITHMETICAL MEAN.

Quarter of head-race treated with salt solution.	Discharge of salt solution, in liters per second.	Weighted mean titration. Table 16.	Arithmetical mean. Table 16.	Ratio of weighted to arithmetical mean.
Upper west (101).....	7.00	6.80	7.36	0.92
Lower west (102).....	6.85	6.35	6.70	0.95
Lower east (103).....	6.80	5.84	5.79	1.01
Upper east (104).....	6.80	5.14	5.00	1.03
Mean for first three tests.....		6.33	6.62	
Means for all tests.....		6.03	6.21	

The reader's attention has been called to the fact that the first and last of Tests *M* were questionable, and it is now also stated that the salt solution was exhausted in the middle of Test 104, so that this test was cut short, with the result that the incident casts doubt on the weighted mean for this test in Table 17. Cutting out these questionable tests, the average variations of the weighted and arithmetical means in Table 17 are, respectively, 96 ÷ 6.33 = 15% and 1.57 ÷ 6.62 = 24 per cent. Thus the variation of weighted values from their mean is only 7½%, although the variation of average titrations in the four quarters of the tail-race is, in some cases, 4, or 5, to 1.

To make a comparison of the mean titrations per liter per second of discharge from the salt-solution tank in Tests *M* with those of Tests 101–104, therefore, we may with some degree of approximation take the product of the titrations by the discharges of the turbines

in the two cases. If these products are doubled they will represent the theoretical titration of the entire discharge of the turbine for 1 sec. when the salt rate is 1 liter of solution per sec., the density of this solution being about 1.18. The results are:

Middle 4 of Tests *M* $2 \times 49\,000 \times 5.39 = 528\,000$ c.c.;
First 3 of Tests 101–104 $2 \times 42\,700 \times 6.33 = 540\,000$ c.c.;

which agree reasonably well for the character of work in the distribution tests. The agreement would have been even better had the middle pair, which are the more trustworthy, of Tests 101–104, been taken instead of the first three. Moreover, these figures are just about what 1 liter of salt solution would give when titrated in the usual manner. For example, the titrations of 10 c.c. of a 100 to 1 dilution of salt solution with distilled water in the two tests have been stated to be

Tests $M = 54.8$, or, 548 000 per liter;
Tests 101–104 $= 53.5$, or, 535 000 per liter.

Therefore, the relative variations of the weighted values from their means in Tests *M* and 101–104 are, respectively,

for Tests *M* $\frac{1}{2}$ of $0.83 \div 5.39 = 8\%$;
for Tests 101–104 $\frac{1}{2}$ of $0.96 \div 6.33 = 7\frac{1}{2}\%$;

which may be attributed in some measure to the variations of the concentrations at different parts of the tail-race, as shown by Tables 13 and 16, in which they are, respectively,

for Test *M*, from 2 to 1 to 100 to 1, in Unit No. 13;
for Tests 101–104, from $1\frac{1}{2}$ to 1 to 5 to 1, in Unit No. 11.

53.—Precision Inferred from Distribution Tests.—An estimate of the order of precision of the regular tests, as to constant errors due to imperfect mixing, may be made from the foregoing discussion. That is to say, we may infer approximately the degree of error in the average concentrations, determined on very carefully conducted tests, from the errors observed in the concentrations of very hasty rough tests.

Without taking extreme values, the following estimate of the variations of concentration of salt in the tail-water in the different quar-

ters of the tail-race, as shown by Tables 13 and 16 for Tests M and 101-104, respectively, are:

Tests M:		Test:	
1.	35 to 1	101.	2 to 1
2.	10 to 1	102.	5 to 1
3.	2 to 1	103.	5 to 1
4.	4 to 1	104.	5 to 1
5.	15 to 1		
6.	84 to 1		
Mean	25 to 1	Mean	4 to 1

Now, if it is assumed that the precision varies directly with the foregoing mean variation, it will follow that a variation in concentration of n to 1 should, as an average, result in a precision giving rise to a systematic error of

$$\frac{8\,(n-1)}{24}\% \text{ for Tests } M, \text{ Unit No. 13} \quad (139)$$

and an error of

$$\frac{7\frac{1}{2}\,(n-1)}{3}\% \text{ for Tests 101–104, Unit No. 11} \quad (140)$$

We have no distribution tests for Unit No. 12, but it may be said that conditions on this unit were intermediate to those on Units Nos. 11 and 13, even to the fact that Unit No. 12 is situated between the other two. Variations of concentration in certain tests on Units Nos. 11 and 13 are shown in Table 18.

Thus, by Equations (139) and (140), we have as the error due to erroneous weighting of concentrations in the best tests on Unit No. 13, by this method,

$$\frac{8 \times 0.045}{24} = 0.015\%,$$

and, for the tests on Unit No. 11, the error is

$$\frac{7\frac{1}{2} \times 0.165}{3} = 0.41 \text{ per cent.}$$

These results are somewhat better than merely relative. They show that the error due to imperfect mixture is very small in the case of Unit No. 13, being negligible, in fact, and that we may expect errors on Unit No. 11 of an appreciable fraction of 1 per cent. The error in the final location of a plotted curve, however, should be less still than these approximate values, which are also to be considered too high, as they undoubtedly contain accidental components.

TABLE 18.—APPROXIMATE MAXIMUM VARIATIONS OF CONCENTRATION OF SALT IN THE FOUR QUARTERS OF THE TAIL-RACE IN CERTAIN TESTS ON UNITS NOS. 11, 12, AND 13.

54.—Time Required to Establish Steady Flow of Salt.—An idea of the variation of concentration for 2-min. averages may be gained from the results of taking a sample every 2 min. from one of the tail-race sampling pumps in Test *A*, July 11th, 1915. The first sample was taken just in time to avoid capturing any salt, immediately before opening the salt-solution valve in the head-race. The samples titrated as follows, in order of number:

1	1305	5	5160	9	5060	13	4930
2	5305	6	5005	10	4920	14	5430
3	5065	7	4995	11	4700	15	5105
4	5090	8	4990	12	4700	16	5100

Units are in hundredths of cubic centimeters titration per ½-liter sample evaporated.

The variations of the concentration from interval to interval are due partly to variations of the rate of introducing the salt solution and partly to those irregularities of the discharge of the turbine which may be expected for intervals as short as 2 min. That is, there are surges in the head-race which produce irregularities of concentration, even

when the salt rate is constant. There was not a sufficiently close connection between time and concentration in Test *A* to admit of a more complete discussion. The important fact to be noticed in this test is that it required but one time interval, 2 min., for the concentration to jump from that of normal head-water, 13.05 c.c., to fully concentrated tail-water, 53.05 c.c. The reason that this latter titration is considerably larger, with only one exception, than all the others is that the salt-solution valve is first fully opened and then adjusted to some predetermined salt rate.

In Test *D* there is a better connection between the time of starting the salt and the time of steady concentration. With possible errors of ½ min., the results are as given in Table 19.

TABLE 19.—TWO-MINUTE, HALF-LITER, TAIL-WATER SAMPLES IN TEST *D*.

24	....	5 590	4 320	

The tests in Table 19 indicate fairly well that it required about 5 or 6 min. for the salt solution to adjust itself to steady conditions after opening the valve. The same conclusion may be drawn from the time required for the decrease in salt rate during the interval from 3-16 to 3-18 to make itself felt in a corresponding decrease of tail-water titration for the interval 3-22 to 3-24. Again, if all the titrations in the fourth column of Table 19 are divided by the salt rate for the interval preceding it by 6 min., a fairly constant ratio results, showing that 6 min. seems to represent the time required for conditions of salt flow

to adjust themselves to changes of a more or less sudden nature. Beginning with the titration, 3 350, for 3-06 P. M., dividing it by the salt rate, 6.41, for 3-00 P. M., two figures of the ratio may be tabulated as follows:

52, 52, 55, 55, 54, 54, 54, 55, 55, 56.

TABLE 20.—MINUTE TAIL-WATER SAMPLES, TEST *U*.

Time. H. M.	Salt rate during preceding interval, in liters per second.	Titration of tail-water sample, in hundredths of cubic centimeters.	Titration, less 1330, for normal head-water, in hundredths of cubic centimeters.	Remarks.
4-35	....	.....	.....	Started minute samples.
36	....	1 345	0	
37	....	1 350	0	
38	....	1 310	0	Started salt solution.
39	?	1 315	0	
40	?	1 430	100	Half-liter samples taken from Pump 25.
41	8	5 300	3 970	
42	8	6 695	5 365	
43	8	6 510	5 180	
44	8	6 485	5 155	

In Test *U*, again, it is seen that it requires 5 or 6 min. for the conditions of flow to become steady. The samples were not continued long enough to make the resulting rate of titration determinable, and the salt rate is uncertain during the first 2 min. of discharge. The final ratio of titration to constant salt rate, carried out to two places, is about 65 (5 160 ÷ 8). This figure could be compared with the ratio, 55, in Test *D*, by taking account of the strength of the salt solution and discharge in the two tests involved. The relative location of points at which samples were taken and the distribution of salt as injected in the head-race are also of moment.

The samples in Table 21 were taken at the end of tests to permit of observations on the weakening concentration when the flow of salt solution is stopped.

In Test 22 it appears that it requires perhaps 8 min. for the salt to disappear completely from the tail-race. The exact instant of closing the salt valve, however, is not recorded, so that there may be an error of a minute or so in the time.

It may be concluded from these results that it requires about 6 or 7 min. to establish uniform conditions of salt flow after changing the

TABLE 21.—TEST 22.—TWO-MINUTE TAIL-WATER SAMPLES.

valve or otherwise altering circumstances in the head-race which produce changes of concentration in the tail-race.

55.—Difficulty in Securing Tail-Race Samples.—It was at first feared that in the tail-race there might be eddies and reverse currents of such a nature as to cause the samples taken from the sampling pumps to be contaminated. It was also feared that there might be reverse currents in the head-race which would allow salt to escape into the head-water of the adjacent units. In either case, the tail-water samples would not be representative.

The first of these sources of error was investigated by shoveling a ton or more of salt into the tail-water at the mouth of the tail-race, some 7 or 8 ft. down stream from the sampling pipes, during which time the sampling pumps were kept in operation. No salt whatever was found in the tail-water samples, thus proving that the water was all flowing outward and that no contamination of samples took place. The actual titrations of ½-liter samples are given in Table 22.

The writer has had experience in tests, however, where the draft-tube and tail-race conditions were not as good as in the case described, the result being that samples of tail-water became instantly contaminated when salt was thrown into the tail-race at a considerable distance down stream from the sampling pipes. In such cases the sampling pipes should be moved back as close to the runner as possible. Even then there will no doubt be occasional cases where it will be found necessary to take samples in the head-race before the feed-water passes through the runner. In this event it will be necessary to take extraordinary precautions to secure a uniform mixture at the distributing system in the head-race, or as quickly after the salt solution is injected into the head-water as possible.

Racks Expedite Mixing.—When uniform mixtures must be effected in the head-race as quickly as possible, it will be found that racks placed in the head-race will assist materially. In many cases the distributing pipes may be placed immediately down stream from the usual trash racks, thus making economical use of the power-house installation. However, the openings of the trash racks are entirely too large to raise sufficient head, and it will be necessary, when the trash racks are to be used in this way, to reduce the openings by suitable fillers, or by horizontal strips across the racks uniformly spaced in the vertical direction.

The head which it is necessary to raise to render the velocity uniform in all parts of the section down stream from the racks will depend on local conditions. Indeed, it may be desirable to have this head adjustable, as in the case of a contract specifying the head on the turbines during the tests. In such a case the openings between the strips must be adjustable.

By changing the head lost through the racks, the head on the turbines can be regulated.

The head raised in such cases must be sufficient to render the velocity of the water practically uniform over the entire cross-section of the head-race. This will require a head of not less than 1 ft. on the racks and even more when the velocities in the head-race in its normal condition are very irregular over the cross-section. Racks raising heads of 4 or 5 ft. are not difficult to construct.

Designers of stilling racks have frequently failed to make the openings in the racks small enough. If 1-in. planks are used, it will generally be found that they should be less than 2 in. from center to center. Overloading must be avoided when raising heads on trash racks.

56.—Efficient Mixing, and Design of Sprinklers.—In order to secure this desirable result, it will be necessary to have as many perforations in the distributing sprinklers as economy and operating conditions will permit. Practically, the size of the holes will be limited by the quantity and quality of the water taken up by the centrifugal pump, and the character of the scale which breaks from the distributing pipes themselves. If the pipes are fitted with flushing outlets, say T's, equipped with valves at the middle or end of each sprinkler, any accumulation of particles of scale or other materials which tend to plug the holes might be occasionally flushed out, but even then some of the holes may become clogged and require individual attention. The safe rule to follow is to have a large centrifugal pump, so that the holes may be made both numerous and large, thus not only preventing the clogging of the holes but also improving the mixture by allowing the centrifugal pump to do a great share of the mixing.

E. W. Schoder, Assoc. M. Am. Soc. C. E., of Cornell University, has made some experiments which will assist in designing efficient sprinklers. The results are given in Table 23.

The diameters given in Table 23 refer to the size of the drill. The diameters of the holes were not measured. The holes were drilled in 2-in. black pipe, and no attempt was made to remove burrs on the inside of the pipe.

The discharges given in Table 23 were measured with jets singly in action, with the tank water surface about 22 ft. above the orifices. A measure of the loss of head in the pipe leading from the tank to the orifices is given by the measured discharge with the orifice pipe

removed. With a difference of level of 20.5 ft., the discharge was 55.5 liters per min., the velocity in the 1-in. pipe being about 6 ft. per sec. We may take 20 ft. as the loss of head for this discharge. With the loss taken proportional to the square of the discharge, the ⅜-in. orifice discharge caused 4.6 ft. loss of head, leaving 17.4 ft. as the approximate effective head. The heads given in Table 23 are based on such calculations.

A photograph of all the jets except the ⅜-in., discharging simultaneously vertically upward, shows the relative heights reached in air, as well as the orifice pipe arrangement. Another photograph shows the tank, the pipe line, and the orifice pipe resting on the bridge spanning the canal.

For the tests on the jets submerged in flowing water, ½ lb. of Prussian blue was dissolved in about 500 gal. of water. This gave an intensity such that one's finger nail became invisible when submerged 1¼ in. beneath the surface in bright sunlight.

During the tests with the colored water, the velocity of flow in the canal was 1.8 ft. per sec. where the jets issued.

The jets were tested issuing horizontally at right angles to the direction of flow in the canal and also issuing vertically. The pulsations in the canal flow caused a lateral swaying of the colored stream at from about 2 to 4-sec. intervals.

When issuing vertically upward, the 2-in. orifice pipe being perpendicular to the flow in the canal, a sample of water near the surface about 4 ft. down stream from the orifice was caught in a bucket. By noting the intensity of the color of this sample, some indication

of the diffusion was obtained. Owing to the large relative dilution, the method fails for small orifices.

In all cases the color seemed to be uniformly distributed across the band for several feet down stream. Below about 6 ft. down stream, the flow pulsations caused localization in the colored stream in swellings of the colored band and separation into two bands. The general appearance, however, was that of a wavy, slowly widening band of blue, somewhat like smoke from a chimney. Table 24 gives the measurements.

57.—As an illustration, it may be observed that the velocity of the water in the canal as it flowed past the orifices in the pipe was about 1.8 ft. per sec., or approximately what it would be in an ordinary open

head-race. The object is to determine the sizes, spacing of perforations, and spacing of sprinkling pipes, so as to obtain as uniform a mixture as possible at the time of injection, thus assisting the mixing as much as possible at the outset.

Fig. 2 shows an efficient system of holes, based on the results of the experiments just described, but, undoubtedly, this can be improved when more extensive experiments are made.

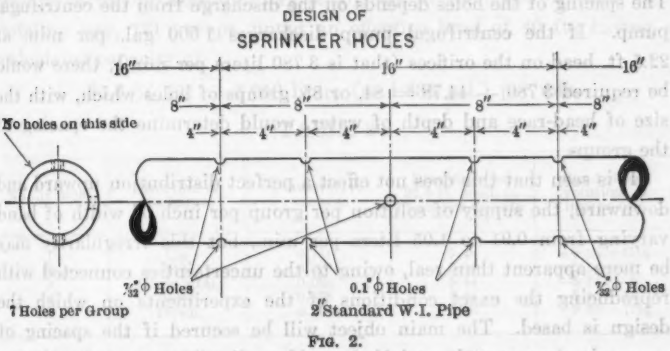

FIG. 2.

The following are the data for a design for sprinkler holes: Intake velocities, 1.8 ft. per sec.; head on sprinkler orifices, 22.5 ft.; discharge of $\frac{7}{32}$-in. orifice, 10.5 liters per min.; discharge of No. 20 drill-hole, 7.46 liters per min.; discharge of No. 40 drill-hole, 2.72 liters per min.; distances out to edges of band supplied with salt by $\frac{7}{32}$-in. hole, 11 and 21 in.; the same for No. 20 hole, 5 and 13 in.; the same for No. 40 hole, 5 and 11 in.

TABLE 25.—DIMENSIONS.

Total.....		44.78					

It will be seen from Table 25 that it is intended to keep the holes under a head of 22.5 ft., and that each sprinkler extending across the head-race at right angles to the current is to supply a band of salt 42 in. wide, extending 21 in. above and below the center-line of pipe. (This neglects the diameter of pipe.) Hence the spacing between the sprinklers should be 42 in. This spacing can be altered by changing the pressure on the orifices corresponding to the desired alteration. The spacing of the holes depends on the discharge from the centrifugal pump. If the centrifugal pump discharges 1 000 gal. per min. at 22.5 ft. head on the orifices (that is 3 780 liters per min.), there would be required $3\,780 \div 44.78 = 84$, or 85, groups of holes which, with the size of head-race and depth of water, would determine the spacing of the groups.

It is seen that this does not effect a perfect distribution upward and downward, the supply of solution per group per inch of width of band varying from 0.91 to 1.05 liters per min., but this irregularity may be more apparent than real, owing to the uncertainties connected with reproducing the exact conditions of the experiments on which the design is based. The main object will be secured if the spacing of groups is close enough, and if the orifices distribute the salt solution well over the entire cross-section of the head-race. There is room for more experimentation on this subject, for, in cases where the tail-water samples must be taken in the head-race, thus necessitating the best possible mixture immediately after the injection of the salt solution, it is imperative to have nice work in the design and operation of the distributing system.

The actual design of the sprinkler orifices is shown by Fig. 3. As there was no special difficulty in securing mixtures in these tests, little attention was paid to rigid rules for the design and operation of the sprinkler system. The orifices were usually under a head of about 40 ft., so that it is hard to state from the results of the orifice tests just how thoroughly the sprinkler system effected a mixture independently of the turbines. A better idea on this point may be secured by examining the results of the distribution tests which have been discussed in Section 52 *et seq.*

58.—Discharge of the Orifices in Tests.—It was intended to follow the general method just discussed for the design of the sprinklers in the tests, but it is believed that the holes were not exactly of the sizes

originally contemplated. Moreover, more or less loose scale in the pipes tended to stop up the holes, thus interfering at times with a full realization of the discharges anticipated. The approximate results for one group of holes are shown in Table 26, from which it will be seen that the total discharge of the eight orifices, under 22.5 ft. head, should be 31.24 liters per min., or about $31.24 \times \sqrt{40 \div 22.5} = 41.6$ liters per min. per group of holes under 40 ft. head. There were 120 groups, with one hole of extra small size at each end of each pipe, totaling, say, 121 groups, under an effective head of 40 ft., having a calculated capacity of

$$41.6 \times 121 = 5\,050 \text{ liters (or } 1\,335 \text{ gal.) per min.}$$

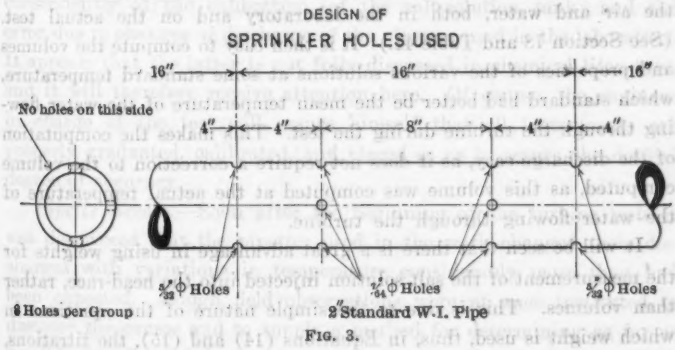

FIG. 3.

The holes, apparently, were of a somewhat different diameter than stated above, but the fact that the discharge of the centrifugal pump, as given in Section 51, and therefore of the sprinkler system, was always less than 1 000 gal. per min., would indicate that a considerable portion of the area of the holes was plugged in the majority of cases.

59.—Leaking Pipes.—Another difficulty experienced in getting representative samples of tail-water was caused by leaks in the ¼-in. risers leading up from the tail-water. The crown of the tail-race arch was from 6 to 8 ft. under water, causing a vertical eddy flowing toward the power-house and against the face of the tail-race wall. This eddy necessarily carried a large portion of tail-water from the adjacent units and river, thus diluting the water next to the power-house wall for a depth of at least 6 ft. As the ¼-in. tail-sample pipes passed up through this water in the early tests, several of the pipes which became leaky on one or two occasions caused a contamination of the samples, which necessitated rejecting the corresponding titrations at such times.

After Test 23, however, the tail-race sampling pipes were moved back into the draft-tube, so that all remaining tests were free from this trouble, the pipes being entirely immersed in the tail-water from the turbine being tested.

60.—Error 7.—Errors Due to Variations of Temperature.—If the temperature varies during a test or series of tests, it will cause changes in the capacities of the measuring instruments, in the properties of the solutions, and in the determinations of the end points of titrations. Hence, it is necessary, when volumetric measurement of samples is used, to observe the temperatures of all the solutions, and of the air and water, both in the laboratory and on the actual test. (See Section 78 and Table 41.) It is then easy to compute the volumes and properties of the various solutions at some standard temperature, which standard had better be the mean temperature of the water flowing through the turbine during the test. This makes the computation of the discharge easy, as it does not require a correction to the volume computed, as this volume was computed at the actual temperature of the water flowing through the turbine.

It will be seen that there is a great advantage in using weights for the measurement of the salt solution injected into the head-race, rather than volumes. This is due to the simple nature of the equations in which weight is used, thus, in Equations (14) and (15), the titrations, p, p_1, p_2, and the rate of weight, w, of salt solution discharged into the head-race, are all that is necessary to know in order to determine W_2, the weight of the water discharged by the turbine. Again, it is this weight which is required to determine the theoretical power with which the turbine is to be charged in computing the efficiency. These equations

are nearly independent of temperature, as the percentages, p, p_1, and p_2, determined by titration, are the same at all temperatures.

For these reasons, the method of weights involved in Equations (5) to (28), inclusive, is recommended as being better suited to turbine testing than the method of volumes used in the later equations. This does not mean that the silver nitrate is weighed. Indeed, the chemical determination is still volumetric, in that the titrations are conducted in exactly the same manner as before, the only difference being that the sizes of samples are determined by weighings.

Finally, any changes in the end-point, or strength, of the silver nitrate, due to changes in temperature during treatment in the laboratory, will be eliminated by the method of special dilutions and group titrations explained in connection with Errors 1 and 2, Sections 46, 47, and 48.

61.—Error 8.—Instrumental Errors.—It is scarcely necessary to enter at length into a discussion of the errors and their net effect which constitute Error 8. There are two errors of this nature, however, to which great attention must be given by the engineer in charge of the test, and these two only will be discussed somewhat in detail. These are the error likely to occur by reason of a change in the capacity, and consequently of the calibration, of the salt-solution tank; and the error due to changes of discharge of the pipettes used in the laboratory. It appears that the latter is not fully discussed in chemical literature, and it will therefore receive attention here. Of course, the engineer in charge of the test will assure himself that all instruments are properly graduated, calibrated, and placed so as to secure the desired degree of accuracy.

Pipette Errors.—Soon after the beginning of the turbine tests it was discovered that the pipettes used in the work changed their discharges with variations in temperature considerably more than had been expected. Rough field observations were at once instituted to discover the causes and to supply a method for determining as far as possible the effect of changes in temperature on their discharge. These tests showed at once that the discharge changed by several times the change in volume of a 10-c.c. pipette, due to a given change in temperature in the neighborhood of 20° cent. After due reflection it was concluded that the change in viscosity, surface tension, cohesion, etc., had a preponderating influence, when the temperature changed,

so as to augment the change in discharge far beyond what the mere change in volumetric capacity of the pipette would account for.

Moreover, it was found, as had been expected, that the concentration of salt in solution had a relatively large influence on the discharge of a pipette, and it became necessary to investigate this source of error, as well as the former. Accordingly, the pipettes were sent to the U. S. Bureau of Standards, Washington, after the turbine tests had been concluded, with the request that they be calibrated with distilled water and salt solutions of 150, 250, and 300 grammes concentration per liter. To ascertain the effect of temperature, each pipette was to be calibrated at three different temperatures, 15°, 20°, and 25°, cent., for its discharge of each of the four solutions specified. By these calibrations it was hoped to discover the law of variation.

Actual calibrations of the pipettes were made by the Bureau only at 20° cent., and the capacities at 15° and 25° cent. were then computed on the basis that the increment of discharge was equal to the increment of volumetric capacity, which was the very thing these desired calibrations sought to avoid. However, it was finally decided to make practical calibrations at the Carnegie Institute of Technology, and these were carried out with considerable success, by actually comparing the volume discharged by a pipette with a fixed volume.

The method of conducting one of these tests was, first, to find a place where a fairly constant temperature could be secured, and second, to discharge the pipette into a burette, the capacity of which had been previously ascertained by calibration. The solution used was made up to a known concentration of salt, except where it was required to test the discharge of distilled water. By making a number of such tests at various temperatures with each solution, it was possible to determine the effects of changes in temperature and concentration.

Fig. 4 shows the results of these tests in diagrammatic form, and Table 27 gives the actual observations. The use of the diagrams will be readily understood, as the discharge of any given pipette can be found at a point on the corresponding diagram opposite the known temperature and vertically above the concentration of the salt solution used, distilled water, of course, being indicated by zero concentration.

62.—*Calibration of Salt-Solution Tank.*—In order to secure the desired degree of accuracy in measuring the salt solution consumed during a test, the solution tank must be so high that a vertical gauge-

board, of sufficient length, can be attached to the side, to admit of readings of the level of the solution in the tank with the necessary precision.

As it will ultimately be required to know the time rate at which the turbine develops power, it will also be necessary to note the time during which the surface of the salt solution falls from one level to another.

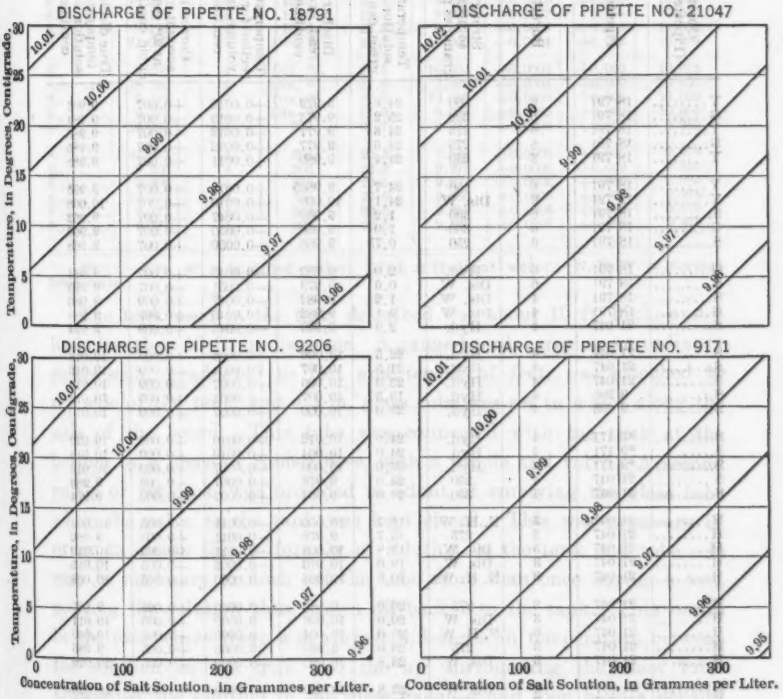

FIG. 4.

This time interval must be determined with the same precision as the quantity of salt solution consumed. Hence, it will be the duty of the engineer to determine the size of the tank and the length of the test, and these two elements will depend on the accuracy with which the timepiece and the tank-gauge can be read, and on the predetermined limit of permissible error.

NOTE.—Dis. W. = Distilled water. Hyd. = Hydrant water. N. H. W. = Normal head-water.

The tank used in the tests described was about 10 ft. high, and a little less than 10 ft. in diameter. A gauge-board, carrying an ordinary gauge-scale, graduated to feet and tenths of feet, was attached to the side of the tank, and a 1-in. glass tube was set in a slot along the axis of the board. This tube was connected with the tank at the bottom by a piece of rubber hose, with a nipple and valve. A second valve, or pet-cock, was provided to admit of emptying the glass tube while the valve to the tank was kept closed. This was necessary in order to insure the uniformity of solution in the tank and tube. It may be necessary to flush out the tube more than once during a test, pouring the solution thus drawn off back into the tank. This would be the case where there was a great difference in temperature between the solution in the tank and the air surrounding the glass tube. Otherwise, the solution in the glass gauge would soon have a density different from that in the tank, thus indicating false surface levels.

On the face of the board, opposite the edge graduated in feet and tenths of feet, a calibration scale was marked off with a lead pencil and carpenter's square. This calibration was made by filling the tank with water and then drawing out equal volumes successively, making a straight horizontal calibration mark after each draft of the standard

volume. This standard volume may be constructed with a piece of 12-in. pipe, or the volume may be determined from a weighing, correcting for temperature variations, in which case an investigation must be made to ascertain whether the water used has any serious deviation in its density from that of distilled water. This latter statement, however, is made only when considering the calibrator as representing a true unit of volume. It is not necessary, for the purpose of efficiency tests, to have the tank or calibrator calibrated to deliver true volumes by weighings of distilled water. The actual feed-water may be used in place of distilled water, any error made in assuming its density to be that of distilled water being compensated by the counter error committed when the theoretical power of the feed-water is calculated on the basis that it is distilled water. Thus, the product of the observed volume, too large in a certain ratio, and the density of distilled water, too small in a like ratio, occur in the formula for efficiency. Therefore, the efficiency is correctly determined, although the discharge derived from the tank observations may be slightly in error. This question is more fully discussed under Error 10, Section 73.

63.—When Does a Test Begin and End?—In operating this tank for a test, the regulating valve leading to the distributing pipes was opened about 7 or 8 min. before the signal for the beginning of the test, which was the ringing of all the bells on the telephone system leading to the different observers. The valve-man then quickly adjusted the valve, by direction of the gauge-reader, until the meniscus of the solution descended in the glass tube at a specified rate, usually about 30 or 40 sec. per calibration division, which corresponds to about 8.46 cu. ft. This usually consumed 2 or 3 min. After this, the valve was adjusted from time to time during the tests so as to maintain, approximately, a uniform rate of discharge.

The gauge-reader then began to note the instants of time when the meniscus passed the successive calibration divisions, the data being entered on the second sheet. One minute before the beginning of the test a preliminary signal was given, and at the beginning there was another signal. The gauge-reader, however, merely draws a line under the last recorded item at the beginning signal, making no other observations. He continues to enter the successive transits of the calibration marks until the signal at the end of the test is sounded,

when he again draws a line under the last recorded item. After taking several more transits, for 1 or 2 min., the flow of salt solution is stopped and the test is at an end.

The adequacy of this proceeding will be seen by noting that there is really no well-defined beginning or end of a turbine test, and that, in fact, the rate of flow of salt solution is substantially the same whether it is determined from the calibration divisions immediately preceding or following the lines drawn when the signals are given for the nominal beginning and end of the test.

The only serious care necessary to take is to see that the rate of flow from the tank is about the same for the first few divisions before and after the beginning, and before and after the end, of the test, so that the time of discharging the standard volume is nearly the same at the first and last divisions, which are indicated on the record by lines drawn under the entries made by the gauge-reader.

If stop-watches are used it will be necessary to run the test for 15 min. in order to limit errors to $\frac{1}{10}$ of 1% with certainty, because, for ordinary field methods, there would be likely to be an error of nearly 1 sec. Stop-watches are not very satisfactory for accurate time observations.

If a chronograph is used, time can be determined with a precision of $\frac{1}{10}$ of 1%, with ordinary care, in 2 or 3 min., or even less. Hence it is clear that, with a given size of tank, a saving of chemical can be effected by the use of a chronograph, where high precision is demanded, as was the case in the tests described herein.

64.—Gravimetric Calibration of Calibrator.—Fig. 5 exhibits the results of a series of calibrations of the iron pipette, or calibrator, which was used in graduating the capacity scale for the gauge-board at the side of the salt-solution tank, as described in Section 62.

It will be seen from Fig. 5 that the three calibrations of the calibrator were made at different times, with a change of observers after the first series. The volumes at 20° cent. computed from the averages of the weighings in the three series are, respectively:

July 13th, 1914	8.4661 cu. ft.
October 22d, 1914	8.4662 cu. ft.
October 27th, 1914	8.4651 cu. ft.

It is possible that this close agreement is principally due to the fact that the weighings were all made on the same scale, which, though for commercial purposes, was carefully adjusted with standard weights

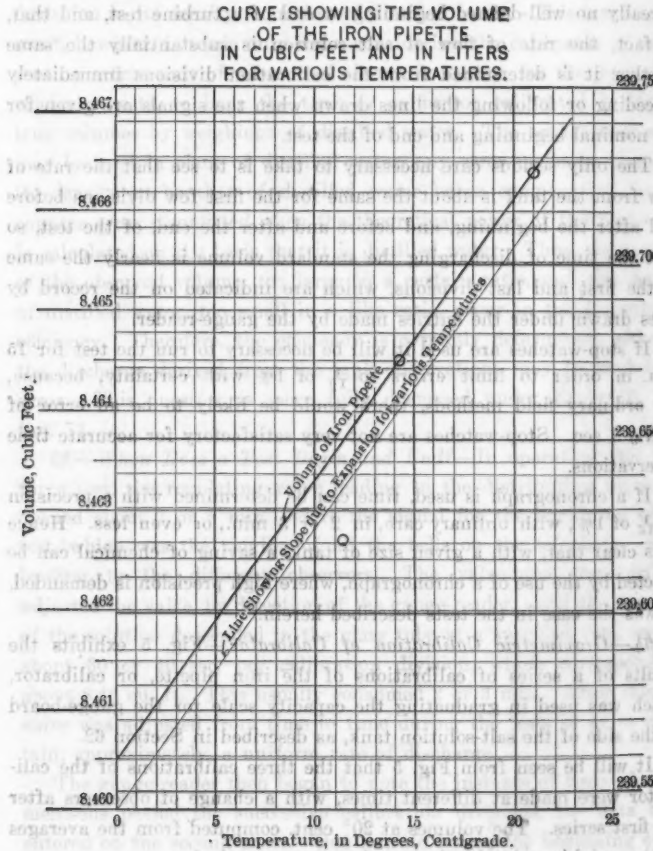

FIG. 5.

prior to each series of weighings. There is no reason to doubt the high precision of these weighings, considered as the results of engineering operations in the field.

TABLE 28.—Calibration of Iron Pipette by Gravimetric Method.

By G. H. Bancroft and R. E. Ward.

8.....	1 605.20	1 077.67	527.53	21.0	P. M.	
Mean..	1 605.508	1 078.043	527.465	21.0		

*Readings 1 and 2 omitted in average.

Weight of 1 c.c. of water at 4° cent. = 1.0 gramme. (From Landolt and Börnstein.)
Weight of 1 cu. m. (= 1 000 liters) of water at 4° cent. = 1 000 kg.
1 cu. m. = 35.31658 cu. ft. (Van Nostrand's Chemical Annual.)
1 kg. = 2.20462 lb. (Van Nostrand's Chemical Annual.)

Therefore, weight of 1 cu. ft. of water at 4° cent. $= \frac{1\,000}{35.31658} = 28.31531$ kg.

or weight of 1 cu. ft. of water at 4° cent. $= 28.31531 \times 2.20462 = 62.4245$ lb.
Weight of 1 c.c. of water at 21° cent. = 0.998019 gramme. (Landolt and Börnstein.)
or weight of 1 cu. ft. of water at 21° cent. $= 62.4245 \times 0.998019 = 62.301$ lb.

Therefore, number of cubic feet in iron pipette at 21° cent. $= \frac{527.465}{62.301} = 8.4664$.

1 cu. ft. = 28.31531 liters.
$8.4664 \times 28.315 = 239.73$ liters in pipette at 21° cent.
Linear coefficient of expansion of iron = 0.0000111 for 1° cent. (Landolt).
Cubical coefficient of expansion of iron = 0.0000333 for 1° cent.
To find volume, in cubic feet, at 20° cent.
Difference in temperature = 21° − 20° = 1°.
$1 \times 0.0000333 = 0.0000333$ cubical coefficient of expansion for 1° cent.
Therefore, volume at 20° $= 8.4664 - (8.4664 \times 0.0000333) = 8.4661$ cu. ft.

In order to facilitate the determination of the volume of the calibrator, or large iron pipette, at various temperatures, the curve (Fig. 5) was prepared, and needs no further explanation.

For the purposes of the tests, the volume of this calibrator will be taken from the curve.

65.—Contents and Delivery of Iron Calibrator.—This large calibrator, or iron pipette, Fig. 21, was constructed on the same principle as the pipettes of the chemists. It consisted of a length of 12-in. pipe, in a vertical position, with a conical top and bottom, so as to admit of as complete a discharge from the bottom as possible while any air within would escape at the top. The top of the upper cone was continued upward with a piece of 2-in. pipe for 18 or 20 in., carrying an ordinary water glass at the side on which was a mark indicating

TABLE 29.—Calibration of Iron Pipette by Gravimetric Method. By J. B. Campbell, C. M. Scudder, and D. C. Walser.

October 22d, 1914. Howe Scale No. 656 849.

No.	Weight, in Pounds.			Temperature of Water, in Degrees, Centigrade.				Time.	Remarks.
	Tank full.	Tank empty.	Water.	From hose.	Tank one-half full.	Tank full, Top.	Tank full, Bottom.

2	1 668.1	1 140.2	527.9	14.3	14.0	14.0	14.0	8:30– 9:30	but dry.
3	1 668.0	1 139.9	528.1	14.0	14.0	14.0	14.0	9:30–10:25	Canal water
4	1 667.7	1 139.7	528.0	15.2	14.2	14.0	14.0	10:25–11:00	was used.
Mean	1 667.93	1 139.93	528.0						Room temperature 18.0° cent.
				Mean temperature 14.14° cent.					

* Reading 1 omitted in average.

Weight of 1 cu. ft. of water at 4° cent. is 62.4245 lb
Weight of 1 c.c. of water at 14.14° cent. = 0.9992514 gramme. (Landolt and Börnstein.)
Weight of 1 cu. ft. of water at 14.14° cent. = 62.4245 × 0.9992514 = 62.378 lb.

Therefore, number of cubic feet in iron pipette at 14.14° cent. = $\frac{528.0}{62.378} = 8.4645$.

Number of liters in iron pipette at 14.14° cent. = 8.4645 × 28.315 = 239.67.
To find volume of iron pipette at 20° cent. in cubic feet.
Change of temperature = 20° — 14.14° cent. = 5.86° cent.
Cubical coefficient of expansion for 1° cent. = 0.0000333.
Cubical coefficient of expansion for 5.86° cent. = 0.000195.
Therefore, volume at 20° = 8.4645 + (8.4645 × 0.000195) = 8.4662 cu. ft.

the proper level of the water for a standard volume. The capacity, when filled to this mark, was a little more than 241 liters, and the discharge from it when filled with canal water was very close to 240 liters, or about 1 liter remained in the calibrator when it was emptied through the conical bottom which was provided with a throttle valve.

The large iron calibrator had the characteristic of a chemical flask, or chemical pipette, in that the content was greater than the delivery. Owing to this difference, the chemical calibration of the contents does not equal the gravimetric calibration of the delivery, but it will be seen that the capacities of the large solution tank, determined chemically and gravimetrically, agree closely, so that by means of the agreement between the results of the two kinds of calibration of the solution tank, the gravimetric and chemical calibrations of the calibrator check each other very satisfactorily, in view of the unfavorable conditions under which the chemical calibrations of both took place. This calibrator, or iron pipette, is more fully described in Part III.

TABLE 30.—Calibration of Iron Pipette by Gravimetric Method.

By J. B. Campbell, C. M. Scudder, and D. C. Walser.

October 27th, 1914. Howe Scale No. 656 849.

No.	Weight, in Pounds.			Temperature of Water, in Degrees, Centigrade.				Time.	Remarks.

8	1 657.4	1 129.3	528.1	11.8	12.0	12.0	12.0	3:37 – 4:15	7.6° cent. temperature of air.
9	1 657.2	1 129.1	528.1	....	12.0	12.0	11.6	4:15 – 4:45	
Mean	1 657.025	1 128.9025	528.0625	11.53	11.25	11.83	10.96		Canal water was used.
				Mean temperature = 11.4° cent.					

*Reading 1 omitted in average.

Weight of 1 cu. ft. of water at 4° cent. is 62.4245 lb.
Weight of 1 c.c. of water at 11.4° cent. = 0.999591 gramme. (Landolt and Börnstein.)
Weight of 1 cu. ft. of water at 11.4° cent. = $62.4245 \times 0.999591 = 62.399$ lb.

Therefore, number of cubic feet in iron pipette at 11.4° cent. $= \frac{528.0625}{62.399} = 8.4627$.

Number of liters in iron pipette at 11.4° cent. $= 8.4627 \times 28.315 = 239.62$.
To find volume of iron pipette at 20° cent. in cubic feet.
Change of temperature $= 20° - 11.4° = 8.6°$ cent.
Cubical coefficient of expansion for 1° cent. change = 0.0000333.
Cubical coefficient of expansion for 8.6° cent. = 0.000286.
Therefore, volume at 20° cent. $= 8.4627 + (8.4627 \times 0.000286) = 8.4651$ cu. ft.

66.—Chemical Determination of Capacities.—The chemical calibrations of the solution tank and the iron calibrator are given in Tables 32-38 and 41, Sections 66, 67, and 68. In order to illustrate the methods more fully, the titrations of all the samples in the case of the calibrator are given in Tables 32 and 33. These tables also show the relative accuracy of the chemical work. In particular, attention must be directed to the fact that two of these calibrations are less trustworthy than the remainder, and that all were executed under more adverse conditions than the regular tests of the turbines. Those in October were mostly performed in a drizzling rain, at the close of a long series of regular tests, and after some of the chemists had returned to their duties at various colleges. Those of November were performed by an entirely different corps of chemists, and during very cold weather, with the atmospheric temperature in the neighborhood of zero, Fahrenheit. The writer supervised the measurement of the 21½ liters of salt solution for the lower level of the tank on November 24th, when its temperature was found to be — 2° cent. This was done in the laboratory where the temperature was nearly 20° cent. higher. If such unfavorable conditions could have been avoided, there is no doubt that a precision surpassing that of the best of the turbine tests would have been secured. As the tests stand, however, they are probably more valuable to the engineer as examples of what can be accomplished under adverse conditions, such as are experienced in the field, than they would have been under more perfect laboratory conditions.

It has been stated that two of the chemical calibrations are not as trustworthy as the others. These are the tests of November 23d, at the upper level of the solution tank, and those of November 25th on the iron calibrator. The first of these was rendered untrustworthy by a failure to measure accurately the quantity of salt solution introduced into the tank from the calibrator. There were, however, nine samples, averaging about 200 c.c. each, taken for this purpose, so that 1 800 c.c. have been deducted from the capacity of the calibrator to ascertain the value of q for this test. In the case of the calibration of the iron calibrator on November 25th, the laboratory work does not check with sufficient exactness to support confidence in the result, as shown by the calculations in Table 31.

The titrations for the upper and lower levels of the large tank show that there was relatively considerable salt still remaining in the tank

after it had been thoroughly cleaned and prepared for the chemical calibration, and that this fact is more apparent at the lower level, as might be expected.

c_1	23.72	28.27	204.82	178.37	303.79	601.16

*Interpolated value from following calculations.

By Equation (49), Section 21, the titration of normal head-water, November 25th, is found, by using the data of Table 34 (Plate XXXVI), to be

$$v_1 = \frac{100.82 \times 5\,326.9 - 535\,030}{99.85} = 20.31,$$

whereas the result should have been about 28 c.c., as may be seen by examining the titrations of the normal head-water on the turbine tests, either observed or computed, see Part IV, or Table 7, Section 46, where it will be found that the titration of the normal head-water was about 26 c.c., as an average, when the strength of the silver nitrate was 1.562, and about 28 c.c. when the strength was 1.45, which is in perfect accord with theory, as

$$\frac{1.562}{1.45} \times 26 = 28.$$

Notice that v_1 for the test of October 14th may be computed to be 23.7 c.c., which is within about 2 c.c. of what it should be, and thus sufficiently accurate.

In order to correct this error for November 25th, slight as the effect is, the value of R' has been computed by using Equation (99), substituting about 28 c.c. for c_1, so that

$$R' = \frac{535\,000}{5\,299} = 100.96$$

Accordingly, this value (more correctly computed = 100.97) of R' has been arbitrarily substituted at the proper place in Table 35, thus giving a somewhat better estimate of the volume. The result, however, is still somewhat doubtful, as the samples of salt solution and other liquids involved do not run as uniformly as they should. Individual titrations of the same solution should agree within about 0.1 c.c., and averages of from five to ten such titrations should check similar averages within $\frac{1}{20}$ of 1% when the total titration of any sample is about 50 c.c. Thus the chemical work of November, as a whole, will not be found so good as that of the earlier tests. These errors, however, are more accidental than systematic, so that curves plotted from numerous tests should not be seriously in error, theoretically being of the same precision as the earlier curves, if there are correspondingly more observations.

To gain a better view of the chemical work, the titrations of the chemical gaugings of the capacity of the iron calibrator are given in Tables 32 and 33.

Average	5 304.1			5 322.7			5 333.7	

In Table 33 the samples are given in the order taken, those marked *B.* coming from the sampling cock at the bottom of the calibrator and those marked *T.* from the top. Thus, it is seen at once that the first three samples of tail-water, taken while the mixture was being stirred, indicate that a perfect mixture had not then been secured, the heavy salt solution naturally settling toward the bottom. The samples were taken from 3 to 5 min. apart, and each has been titrated twice in the laboratory, as may be detected by examining the titrations in pairs, which are on the same line. Therefore the tail-water samples in parentheses have been omitted from the averages of the titrations. In the case of the special dilutions, the prefixed numerals relate to the salt solution sample with which the normal head-water was mixed. The second set of these, which was made from Sample 3, titrated less than the dilute salt solution, which is inconsistent. In fact, all these samples titrate too low, as they should run, on the average, about 0.28 c.c. higher than the salt solution titration, which latter averages 5 304, or they should average about 5 332, instead of 5 322.7 as they do. This discrepancy has already been discussed in determining a more probable value of R'. For these reasons, the titrations 5 260 and 5 263 have been excluded from the average, and the last set, though throwing too much weight in favor of No. 4 sample, is allowed to be included, as it is clear that the titrations of special dilutions are all too low.

Comparing now the results of the titrations in Tables 32 and 33, it will be easy to see that the former is far the more trustworthy, and for this reason a second computation of the volume of the salt-solution tank in the tests of October and November has been made, using the calibration of the calibrator of October 14th only. These latter

calculations are undoubtedly the more correct, especially that for November 23d, because there is no question as to the quantity of salt solution introduced into the salt-solution tank in that test.

The detailed calculations appear in Tables 34 (Plate XXXVI), and 35. In compiling Table 34 the volumes of samples of tail-water and special dilutions have been supposed to vary with changes in temperature in the same ratio as the specific volume of distilled water. Although this is sufficiently accurate in all cases, yet, in computing the turbine tests, it was decided to take the actual densities of tail-water and special dilutions as closely as they could be found, by using Table 1 and Plates XXXIII, XXXIV, and XXXV. The tabular densities of the salt solution have been utilized in the same way, and, as the ratios, only, of these densities are used in the calculations, no serious errors result, even where the true densities differ appreciably from the tabular values, due to the fact that commercial salt was used instead of pure NaCl.

We are now in a position to compare the best results of the chemical calibrations of the salt solution tank with the results of the calibrations based on the gravimetric determination of the volume of the calibrator in Section 64.

Plate XXXVII shows the graduation marks on the gauge-board at the side of the solution tank. Each calibration division represents a calibrator-full of water, as it was drawn from the tank, the graduation marks having been placed on the scale by using a lead pencil and carpenter's square at the level of the meniscus, which was plainly visible in the 1-in. glass tube in the slot along the center of the board.

There were three calibrations on different dates, as follows:

1.—Long marks, July 16th, 17th, 18th, 20th, and 21st, by Messrs. Ward and Bancroft;

2.—Short marks, July 30th, 31st, and August 1st, by Messrs. Ward and Bancroft;

3.—Intermediate marks, October 20th, by Messrs. Ward and Campbell.

In the chemical calibration of October, the upper level of the water in the tank was at graduation mark 12 of the short marks before the salt solution (1 calibrator-full, less about 1 800 c.c. for samples) was introduced, thus filling the tank nearly to graduation 11. At the lower level the water surface was at graduation 70 of the short marks.

In the chemical calibration of November, at the upper level, the water surface was at the point marked *A*, Plate XXXVII, slightly below graduation 13 of the long marks; and, at the lower level, the water surface was at graduation 70 of the long marks.

Therefore, to compare the two chemical calibrations, it is necessary to reduce them to the same levels, which, for definiteness, will be at graduations 12 and 70 of the long marks. These corrections, therefore, are due to discrepancies of 0.17 in. (scaled from Plate XXXVII) between the long and short marks for graduation 70, and 0.03 in. between the long and short marks for graduation 12, the average lengths of division for 1 calibrator-full at these levels being, respectively, 1.41 and 1.49 in., giving percentage corrections of $17 \div 1.41 = 12\%$ and $3 \div 1.49 = 2\%$, correspondingly. The capacity of a calibrator being approximately 240 liters, the corrections in liters are:

For upper level = 2% of 240 = 5 liters;
For lower level = 12% of 240 = 29 liters.

In both cases these corrections should be deducted from the volumes given by the chemical calibration of October, to reduce to the proper graduation mark.

In the case of the chemical calibration of November, a correction must be added to the volume at the upper level to obtain the corresponding volume at the long mark for division 12. The correction to reduce from the mark, *B*, to long graduation mark 12 is due to a discrepancy of level of 0.3 in. in an average length of 1.50 in., or exactly 20% of 1 calibrator-full, which amounts to 48 liters to be added to the November volume at the upper level.

Table 36 gives the adjustment of the figures from Table 35.

It must be remembered that the November calibration here is the more truthworthy, being 13 875 liters between graduation marks 12 and 70.

To obtain figures for comparison from the gravimetric calibrations of the calibrator and the calibration scales of Plate XXXVII, an account must be made of the temperatures at which the scales on the drawing were made. The calibration at long marks in July was made at an average temperature of 20½° cent.; and those in October, at the intermediate marks, were at 13½° cent. The short marks will be neglected at present for the reason that there is some doubt about them, as will

appear in the next section. The capacity of the calibrator in this case is about the same as in the case of the long marks, the temperature being 19¾° cent. Thus

Volume of calibrator by Fig. 5 = 239.72 liters at 20½° cent.
= 239.66 liters at 13¼° cent.,

from which

(July 18th) 58 calibrator-fulls at 20½° = 13 904 liters.
(October 20th) 58 calibrator-fulls at 13¼° = 13 900 liters.

TABLE 36.—ADJUSTMENT OF VOLUMES DETERMINED CHEMICALLY FOR COMPARISON WITH VOLUMES DETERMINED WITH THE CALIBRATOR AND ITS OWN GRAVIMETRIC CALIBRATION.

	October 15th.	November 23d.
Volume at upper level. Table 35 (based on volume of calibrator, October 14th only)	16 100*	15 975
Corrections from above	— 05	+48
Resulting volume for long mark 12	16 095	16 023
Volume at lower level. Table 35	2 167	2 148
Correction from above	29	.....
Resulting volume for long mark 70	2 138†	2 148†
Net volume between long marks 12 and 70, 58 calibrator-fulls	13 957	13 875

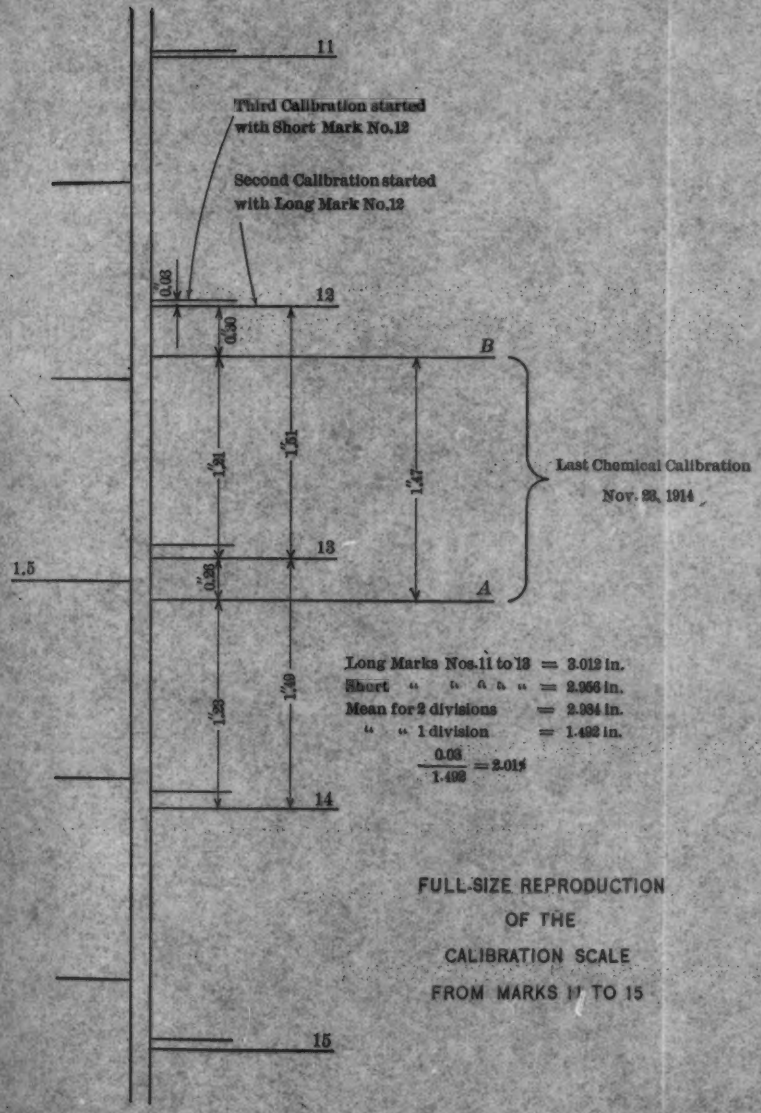
* The reader is reminded that there was no exact measurement of the quantity of salt solution taken for samples from the contents of the iron calibrator while it was being emptied into the salt-solution tank on October 15th.

† An error of 0.004 or 0.005 ft. in reading the tank gauge would introduce an error of 8 or 10 liters in the volume computation.

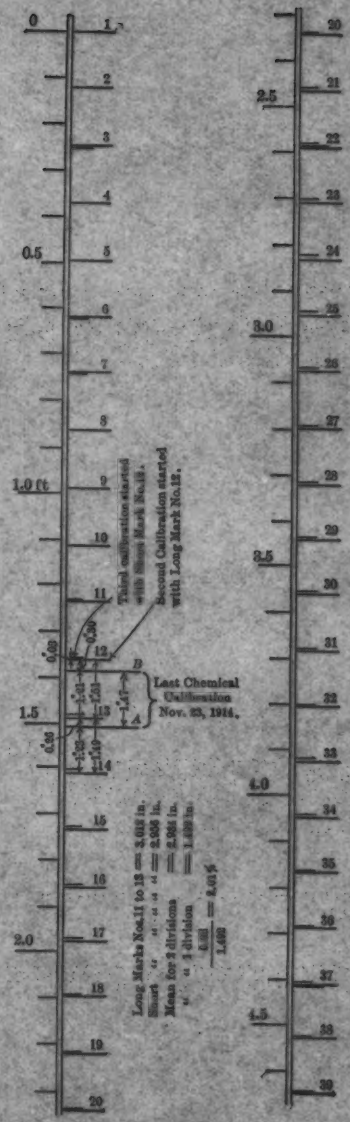
Now, the third calibration (intermediate marks) started with short mark 12 and ended about 0.05 in., or 5 ÷ 1.41 = 3½%, of 1 calibrator-full, 8¼ liters, above graduation mark 70. That is to say, the third calibration indicates that the volume from long mark 12 to long mark 70 at the time of the third calibration was 13 900 + 8¼ — 5 = 13 903¼ liters, or the two calibrations (first and third) check within ¼ liter, 58 calibrator-fulls in July, therefore, being 13 904 liters, which is what the volume of the tank from long mark 12 to long mark 70 was in July by the calibration at that time. Hence, the following comparison results:

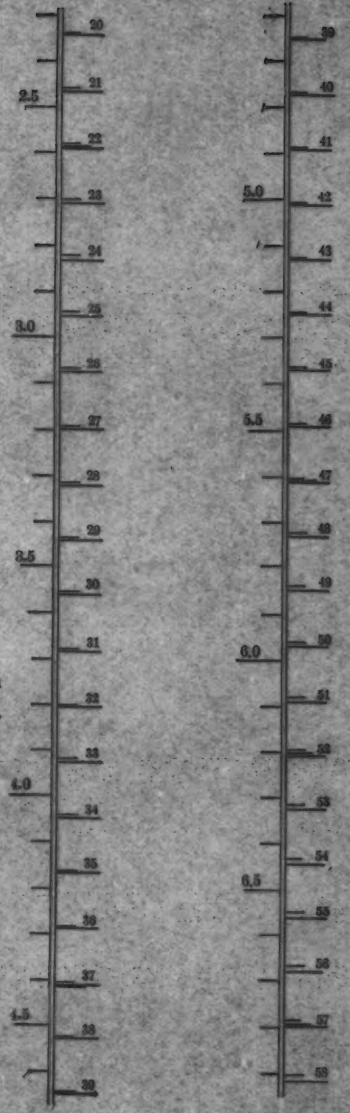
Volume of tank between graduation marks 12 and 70, of the first calibration by the calibrator, based on both the first and third calibrations..... 13 904 liters.

Volume of tank between these same marks..... (October).... 13 957 "
but by the chemical method..... (November). 13 875 "
Mean of last two..... 13 916 "



FULL-SIZE REPRODUCTION
OF THE
CALIBRATION SCALE
FROM MARKS 11 TO 15





CALIBRATION SCALES
AT SIDE OF
SALT SOLUTION TANK

Long Calibration Marks, No.1, used on Tests *G, H, I, K, L, N,* and *O* on Unit No.12.
Short Calibration Marks, No.2, used on all other tests.

Calibration No.1. Long Marks.
Made July 16th, 17th, 20th, 21st, and 22nd, 1914.
Average Temperature = 22.15° Cent.

Calibration No.2. Short Marks
Made July 28th, 31st, and August 1st, 1914.
Average Temperature = 19.64° Cent.

Calibration No.3 Marks ¾ in. long.
Made October 19th, 1914.
Average Temperature = 13.25° Cent.

Long Marks Nos. 69 to 71 = 2.956 in.
Short " " " " = 2.839 "
Mean for 2 divisions = 2.898 "
" " 1 division = 1.414 "
0.17 / 1.414 = 12.02%

Apparently, therefore, there was no change in volume of the 58 divisions of the tank by the first and third gravimetric calibrations, but there is considerable change, 82 liters in 13 900, or 0.6%, by the two chemical calibrations, the tank being smaller in November than in October. Attention has been called to the fact that the chemical calibration at the upper level in October is not so trustworthy as the later one, on account of the failure to measure exactly the quantity of salt solution taken from the calibrator for samples. If we neglect this, we may say that the chemical determination indicates a volume of 13 875 liters in November, as against 13 904 liters in July, by means of the calibrator, or only 0.2% discrepancy, and this is in the direction which one might suppose such a change would be.

67.—*Degree of Precision in Turbine Tests.*—Attention has been called to the fact that the chemical calibrations were not conducted under such favorable conditions as the best of the turbine tests. Accordingly, these discrepancies of 0.2 to 0.6% are larger than the discrepancies of the best turbine tests by a considerable margin. However, there is one important conclusion to be drawn from these chemical calibrations, namely: There was no serious systematic error involved in the chemistry and laboratory operations during the turbine tests. In so far as the chemical procedure was concerned, the results of the turbine tests are correct to a small fraction of 1 per cent.

It may also be added that the mean of the two chemical tests checks the mean of the first and third calibrations by the calibrator within 0.1 of 1 per cent. If the second calibration with the calibrator is included, the error is still less, but no importance can be attached to these facts. The calculation, however, follows:

Fifty-eight calibrator-fulls in the second calibration (short marks) at 19¼° cent. are equivalent to $58 \times 239.716 = 13\,903\frac{1}{2}$ liters. To reduce this to long marks 12 and 70, simply add, algebraically, the corrections due to the discrepancies in elevation of the corresponding short marks, which have already been ascertained, namely, 29 and 5 liters, respectively. Thus the volume between the long marks 12 and 70, based on the second calibration with the calibrator is $13\,903\frac{1}{2} + 29 - 5 = 13\,928$ liters.

The mean of the values of the volume between divisions 12 and 70, based on all three calibrations with the calibrator, therefore, is the mean of 13 904, 13 904, and 13 928, which is 13 912 liters, as com-

pared with a mean of 13 916 liters by the two chemical calibrations. This omits entirely the last chemical calibration of the contents of the calibrator because of the inconsistencies in the chemical treatment previously mentioned.

We might make other comparisons by various combinations of results, but these would not improve matters, even if they gave closer agreement between the results by the two methods. The writer prefers to adopt the values which can be least criticised. These are based on the calibrator volume determined on October 14th, the tank calibration at the upper level, on November 23d, and the mean of the two calibrations at the lower level, on October 16th and November 24th, both of which appear to be trustworthy. Neglecting the effects of differences of temperature, this estimate would be:

Volume at upper level, November 23d.....16 023 liters
Mean at lower level October 15th, November 23d.. 2 143 "

Probable volume, 58 divisions.....13 880 liters.

This agrees well with the gravimetric calibrations of either July or October, the mean of which is 13 902.

To make matters still clearer, Table 37 gives a compilation of the titrations of the samples taken during the chemical calibrations of the large tank.

It is apparent from Tables 37 and 38 that the chemical work of November was not as good as that of October, and, perhaps, one of the most potent reasons therefor is the fact that most of the outdoor work in November was done in bad weather, with the thermometer near zero, Fahrenheit. On the other hand, there is a larger number of titrations in the November work, which would tend to reduce the residual accidental error in the laboratory observations.

As a general rule, two or three chemists performed the titrations in pairs from the same sample, mates appearing on the same horizontal line of the tables.

In closing this section it may be remarked that there is no basis for comparing the gravimetric with the chemical calibration of the calibrator. There is considerable difference between the two, but this is as it should be, as the gravimetric calibration was a measure of the delivery and the chemical calibration was a measure of the total contents of the calibrator. The latter should exceed the former, as it does, but there were no weighings of the total contents of the calibrator, so that there is really no basis for comparison. The evidence is that the two methods can be made to check each other within a few hundredths of 1%, even when the operations are not nearly so refined as the more painstaking work of a laboratory research.

68.—Changes in the Capacity of the Tank.—The general method of calibrating the solution tank was explained in Section 62 *et seq.*

Plate XXXVII is a *fac simile* of the calibration scale taken directly from the gauge-board after it had been removed from the tank at the close of the tests.

The first calibration was made on July 16th, 17th, 18th, 20th, and 21st, 1914. The corresponding scale is indicated on Plate XXXVII by the longest of the graduation marks. The second calibration, July 30th, 31st, and August 1st, 1914, is indicated by the shortest marks; and the third calibration is indicated by the marks of intermediate length.

The first and second calibrations covered the entire scale from graduation 1 to graduation 76, but the third calibration began at graduation 12 and continued to graduation 70, a graduation mark being made at every fifth division.

It will be observed that the first and third calibrations agree remarkably well, and that the second runs with increasing divergence on the side of larger capacity when compared with either of the other two. There is, however, a close agreement between the first and second calibrations from graduation 1 to graduation 45 or 46, and from 52 or 54 to the end of the scale.

Thus all the calibrations agree well with one another except that the first and second calibrations do not agree at points between 45 and 54. Therefore, it must be concluded that there was either an actual change in the calibration scale, from 45 to 54 between the first and second calibrations, followed by a return to original conditions, or an error was made along this part of the scale during the second calibration.

It is not to be imagined that the temperature changes could affect the calibrations so as to cause any such differences. The tank was of 2-in. white pine, with steel hoops. It was about 10 ft. high and about 9 ft. 4 in. in diameter at the top and 9 ft. 8 in. diameter at the bottom, inside measure. The temperatures and corresponding average volumes of the calibrator in the first and second calibrations are given in Table 39. This shows that the changes in the capacity of the calibrator are limited to 0.01 or 0.02 of 1%, which is considerably within the limit of error in the observations during the turbine tests. Indeed, the indications are that the volume of the tank was much more consistently constant than could have been anticipated. The third calibration, considered in conjunction with the first, shows that the volume of the tank was the same on both occasions, and the second calibration points to either a change or a slight error between graduations 45 and 54.

TABLE 39.—Average Volume of Calibrator.

Date.	Graduation.	Temperature, in degrees, centigrade.	Average volume of calibrator, in liters.
First Calibration:			
July 16th	1-14	21.0	239.73
17th	14-32	21.4	
18th	32-45	21.0	
20th	45-60	19.0	239.71
21st	60-76	19.0	
Second Calibration:			
July 30th	1-10	19.5	239.715
31st	10-44	19.8	
August 1st	44-76	19.6	
Third Calibration:			
October 20th	12-70	13.2	239.665

The writer is inclined to the view that each calibration should be considered as standing by itself, as being the best criterion of the actual volume of the tank at the time of the calibration, any error in utilizing the calibrations being in all probability less than 0.1 of 1 per cent. Therefore, the new calibrations were used as soon as made, the older ones being disregarded in the ensuing turbine tests.

69.—Effect of Painting on the Capacity of the Tank.—Prior to the time of painting the salt-solution tank, it was found that readings, taken night and morning, showed variations of from 0.03 to 0.06 ft. Apparently, there were diurnal changes in capacity due to periodical variations of temperature, humidity, and other atmospheric conditions. Therefore, it was decided to give the tank two coats of white lead.

After the tank had been painted, these fluctuations of water level became markedly lessened, and toward the close of the tests the capacity of the tank became almost fixed.

Table 40, compiled from the record, shows characteristic observations on the level of the water in the tank.

The solution drawn off between the observations of September 25th and 26th was consumed in running some tests on the large centrifugal pump to ascertain the power required for this purpose during a regular turbine test.

TABLE 40.—OBSERVATIONS ON LEVEL OF WATER IN SALT-SOLUTION TANK.

Condition.	Date.	Time.	Gauge reading, in feet.	Remarks.
Before painting.	July 8th.	9.40 A. M.	10.33	
	" 8th.	3 P. M.	10.365	
	" 9th.	3 P. M.	10.38	
After one coat of white lead.	July 15th.	2 P. M.	10.08	
	" 15th.	5 P. M.	10.04	
	" 16th.	8 A. M.	10.02	
	July 20th.	5 P. M.	7.13	
	" 21st.	8 A. M.	7.13	Tank filled.
After second coat of white lead.	July 21st.	5 P. M.	10.11	
	" 22d.	8 A. M.	10.10	Still later, after refilling.
	July 28th.	4 P. M.	10.53	
	" 29th.	8 A. M.	10.50	
	" 29th.	1.30 P. M.	10.52	
	" 29th.	5.30 P. M.	10.53	
	" 30th.	8 A. M.	10.52	
Another series.	August 5th.	2 P. M.	10.48	
	" 5th.	5.30 P. M.	10.48	
	" 6th.	8.30 A. M.	10.47	
	" 6th.	3.15 P. M.	10.49	
	" 7th.	8 A. M.	10.49	
Last long series on same tank full of salt solution.	September 18th.	5.30 P. M.	9.95	
	" 19th.	8.30 A. M.	9.95	
	" 19th.	12.01 P. M.	9.95	
	" 21st.	8.30 A. M. and P. M.	9.95	
	" 22d	8.30 A. M. and P. M.	9.95	
	" 23d	8.30 A. M. and P. M.	9.95	
	" 24th.	8.30 A. M. and P. M.	9.95	
	" 25th.	8.30 A. M. and P. M.	9.95	
	September 26th.	8.30 A. M. and P. M.	9.40	Some salt solution drawn off.
	" 27th.	8.30 A. M. and P. M.	9.40	
	" 28th.	8.30 A. M. and P. M.	9.40	

These observations, together with the results of the calibrations, show that there were no serious variations in the capacity of the salt-solution tank during the series of tests on the turbines.

70.—Care of the Tank.—The principal rule to enforce in the care of the tank is as to the load it carries. If it is always kept filled with salt solution to about the same level during a series of tests, its volume has no tendency to change seriously. If there is no system in this matter, it will be uncertain as to whether there have been serious changes in capacity.

Accordingly, it was a rigid rule, in the tests described, to keep the tank filled with salt solution as continuously as possible. It was always the aim to fill the tank with salt solution immediately after each test,

whenever possible, and on only a few occasions was it allowed to stand over night filled with fresh water instead of salt solution. At no time was it allowed to remain empty, or partly full, during the night, or for any longer time during the day than could be avoided.

The writer attributes the constancy of volume of the salt-solution tank in large measure to the fact that it was kept continuously full of salt solution.

71.—The calibrations of the electrical instruments are not reproduced in this paper, but are filed in the Library of the Society for reference by any one interested.

72.—Error 9.—Time.—An ordinary watch will keep time sufficiently well for the purpose of turbine testing, even when time is to be determined to within 0.1, or even 0.01 of 1% in precision. There are 1 440 min. in a day, so that 1.44 min., or 1 min., 26.4 sec., represents 0.1 of 1% and 8.64 sec. represents 0.01 of 1 per cent.

Therefore, it may be stated that an ordinary watch in only fair regulation will run within 0.1 of 1%, but it must be in good regulation to run within 0.01 of 1%, and it should be compared with a reliable standard before and after each test, when it is desired to ascertain time more exactly than within 0.1 of 1% in precision.

A much more serious matter than the systematic error in the rate of the watch is the accidental and personal errors of observation. These have been discussed to some extent in Section 63, and will not require extended comment here, except to call attention to the possibilities of watches and chronographs.

There is considerable doubt about the rates of watches operating near large electrical machines, especially in case of direct current. For this reason, it may be advisable, in some cases, to use a chronograph driven electrically by a clock at a distance. A chronograph may be advisable on other grounds, especially where tests can be of short duration, thus saving labor and chemicals where the chemical method is used.

When a watch is used it must be considered that accidental errors approaching 1 sec. are not only possible but probable, even with a stop-watch. Moreover, stop-watches are likely to change their rates by 1 or 2 sec. in 15 or 20 min., unless they are very carefully handled, and there is a high probability of one failing entirely in the course of a test. It is important, therefore, where reliance is placed on stop-watches, to keep several running during a test—not less than three—

where it is important not to lose the observations altogether, and these watches should be rated and compared before and after each use.

In order to secure sufficiently accurate time observations with stop-watches, it must be considered that an accidental error of at least 1 sec. may be made in starting and stopping the watch, or the split-second hand where a split-second watch is used, unless several observers with different watches observe at both start and finish. In this case an idea of the error of observing can be gained from the separate estimates made by the different observers; but, in the case of only one watch, the error must be counted at 1 sec., thus determining the length of a test when the limit of error is decided on.

Therefore, if the limit of the degree of error is 0.1 of 1%, it will be necessary to run the test for 1 000 sec., say, 16 or 17 min. Perhaps 15 min. is the limit, in round numbers. Accordingly, the regular turbine tests described lasted from 15 min. to 1 hour.

The kind of watch most convenient for such work has two hands: one is driven continually from the time the watch is started until it is stopped; the secondary hand moves in coincidence with the primary until it is stopped at any instant by pressure on a small stop. A second pressure on the stop causes the secondary hand to spring into coincidence with the primary again, and these operations may be repeated as often as necessary. Consequently, as many time readings as desired may be made by such a watch, and this without losing account of the correct time, which would be the case by stopping the entire mechanism, as is necessary with many kinds of stop-watches.

Another advantage may be gained, where the time is required in seconds, by having the dial graduated centesimally, each division of what is usually called the minute-scale thus representing 100 sec. Not many watches of this kind have been made, but the writer succeeded in having one divided in this way, and found that it pays well, by reducing the labor of final calculations.

73.—Error 10.—Elimination of the Density of Feed-Water.—The density of the feed-water for the turbine may not be known. If the test is purely for efficiency, where the actual discharge of the turbine is required merely as a factor in the efficiency formula, the density of the feed-water need not be determined, if the units of volume of the calibrator and tank are computed from weights of actual feed-water in conjunction with densities of distilled water.

The error thus made may be eliminated in the efficiency calculation by charging the turbine with theoretical power based on the densities of distilled water and the observed discharge, as given by the observations on the calibration scale at the side of the tank, the counter-errors, thus made, neutralizing each other in the efficiency computation.

Thus, if the density of distilled water is d, that of the actual feed-water is d_1, and the weight of the contents of the calibrator when filled with feed-water is w, the true volume and the computed volume, based on the density of distilled water, are, respectively:

$$\text{True volume of calibrator} = w \div d_1.$$
$$\text{Computed } \text{“} \quad \text{“} \quad \text{“} \quad = w \div d.$$

Hence the ratio of the computed to the true volume is $d_1 \div d = 1 + e$, where $100e$ is the percentage of error relative to the true volume. That is, all volumes measured by the calibrator will be affected by the same percentage of error; or, if V is the true discharge of the turbine during a test, then the observed volume will be:

$$\text{Observed volume} = V\,(1 + e).$$

Now, the power with which the turbine will be charged, based on the density of distilled water, and the discharge determined by the calibrator, is:

$$\text{Observed power} = \frac{(V\,[1 + e])\,d\,h}{550} \quad \ldots\ldots\ldots\ldots (141)$$

where h is the head acting on the turbine;

but $$d_1 = d\,(1 + e),$$

as has just been shown, therefore,

$$\left.\begin{matrix}\text{True power charge-} \\ \text{able to turbine...}\end{matrix}\right\} = \frac{V\,d_1\,h}{550} = \frac{V\,(1 + e)\,d\,h}{550} \quad \ldots. (142)$$

or, this method of calibrating the tank, observing the tests and computing the results, gives the true efficiency, though there may be a small error in the volume of the tank, and therefore of the discharge, as shown by the calibration scale on the gauge-board.

74.—Error 11.—Omission of Weight of Salt.—When the method of weights, Section 10, is used, there is no error due to the omission of the weight of salt, as the total weight of solution passing through the turbine is determined by the equations based on weights (Equations (11) to (28), inclusive). There may be an insignificant error, however, due to

the fact that the tables are based on chemically pure NaCl, whereas the salt used is of commercial grade only. This error is entirely negligible.

In the case of the volumetric method, however, beginning with Equations (38), where the methods of Section 73 are used, the weight of the salt contained in the dosing solution is neglected and results in a corresponding error. This error was negligible in the tests involved herein, as the following considerations show:

As a usual case, the discharge of the turbines was about 1 550 cu. ft. per sec., and the rate of dosing was about 0.25 cu. ft. per sec., so that the ratio of dilution was about 1 to 6 200. The strength of the salt solution was about 25%, and its density about 1.18, so that the weight of salt per liter was $0.25 \times 1.18 = 0.295$, say, 0.3 of the weight of distilled water $= 0.3 \times 62.4 = 18.7$, say, 19 lb. per cu. ft. of salt solution, of which one-fourth, or, say, 5 lb., is the rate of salt injection per second. The total weight of water passing through the turbine is approximately

$$1\,550 \times 62.4 = 96\,700, \text{ say, } 100\,000 \text{ lb. per sec.}$$

Therefore, the error introduced by omitting the weight of the salt is, relatively, about $5 \div 100\,000 = 0.00005 = 0.005\%$, which is negligible for work of only 0.1 or even 0.01 of 1% precision.

75.—Error 12.—Sources and Sinks for Chemicals.—In the language of the mathematicians, there may be sources or sinks intermediate to the dosing and sampling stations, where chemical is either introduced into or lost from the water being measured. These gains or losses of chemical may be due to natural causes, such as mineral springs in the bed of the stream, or to artificial causes, such as result from the operations of industries along the channel.

If there is a mineral spring down stream from a leak or sink, where the flow of the spring and the discharge of the leak are about equal, the net result is an introduction of chemical between the two stations. In some such manner there might be a loss of chemical.

Where great accuracy is required, an investigation should be made to ascertain whether there are any such sources or sinks intermediate to the dosing and sampling stations. This is easily accomplished by taking samples, preferably simultaneously at the two stations. If serious discrepancies are found among the titrations of samples, appropriate

alterations in the scheme for measuring the flow of the water must be made.

In some locations it may be found necessary to test samples frequently to see whether there are changes in condition taking place from time to time, and this may have to be done during tests. Of course, it will usually be found possible to avoid this difficulty, but it should be carefully remembered when a discharge measurement is contemplated.

76.—Error 13.—Sources and Sinks for Water.—These are similar to those discussed in the preceding section, but are especially to be feared in the case of a turbine test. It is nearly always the case that there are leaks of more or less consequence through the concrete walls of penstocks and turbine pits. Besides this, in many cases the draft-tubes fail to discharge water throughout the entire cross-section. This results in eddies and negative currents which may introduce water containing more or less salt than should result from the salt injection intended for the test.

One of the easiest ways to examine this source of error is to shovel a considerable quantity of salt into the tail-race down stream from the tail-race sampling pipes. During the time that the salt is being shoveled into the tail-race the sampling pumps are kept in operation and samples of the tail-water are secured in the tail-race while samples of normal head-water are taken simultaneously in the head-race. If all samples titrate alike, it is safe to say that no tail-water was washed back into the tail-race during the test. A single test of this kind, however, may not be conclusive for all gate openings and turbine speeds. It may be necessary to repeat the test under a variety of conditions.

The best safeguard against this difficulty is to place the tail-sample pipes at a point in the system where the water is known to flow in only one direction throughout the entire cross-section. These pipes may even be placed in the head-race a short distance below the dosing pipes, but in this case, as the advantage of the mixing power of the turbine itself is lost, it will be necessary to design and operate the dosing system very carefully so as to secure as perfect a mixture as possible at the outset. See Section 56.

This method has been used with a fair degree of success in a case where the dosing solution was supplied to the distributing and sprinkling system by a centrifugal pump of insufficient capacity.

It is quite important in such cases to have a centrifugal pump and sprinkling system which will force the jets of water to a considerable distance laterally, in order to secure good mixtures.

77.—*Error 14.—Errors in Tables and Data.*—There may be some slight errors in the salt tables and diagrams (Table 1 and Plates XXXIII, XXXIV, and XXXV). These may be relatively large for the smaller values of the quantities tabulated. Thus, the theorem of Section 23, that a molecule of salt always displaces a portion of the water in which it is dissolved may need revision when more accurate data are available.

However, the results of the tests and tank calibrations described herein are of such a character that it may be concluded there was no error in respect to the accuracy of the tables which affects the results appreciably.

78.—*Error 15.—Theory.—Simplified Calculations.—Advantages of Measuring Samples by Weight.*—One of the best chances for error lies in the calculation itself. The simpler the calculations are made the less chance there is for errors. In Section 10 attention was directed to the system of weighing samples rather than measuring them by volume. In order to make the advantages of this method more apparent, the following calculation of the weight of the contents of the calibrator (November 25th, Table 35) is given, with a final reduction to volume for the purpose of checking the result determined in that table, 241.02 liters at 4° cent. The check is not absolutely perfect, owing principally to the fact that in computing the data for the calculation corresponding to that of the table, the weight, W'_2, has been taken at 860 grammes and the weight, W', at 10 grammes, instead of 1 003.6 and 11.671 grammes, respectively, which correspond more exactly to the figures of the table. Had these figures been taken, the ratio, F', would have been 85.99, instead of 86, and the result would have checked the figures of Table 35 very closely. The rounded weights have been chosen, as it is quite probable that the samples would be weighed in about that manner, it being a simple matter to adjust the quantity of solution to a given weight. It would be better practice, however, to adjust the weights so that all samples would titrate alike. Hence the titration, t, has been inserted, which represents the titration of 11.7 grammes of salt solution, this number being, aproximately, a multiple by ten of the density. The advantages of this method will undoubtedly

be appreciated after an examination of Table 41, which, with but few additional reductions, would include all the necessary data and the final calculations, thus displacing both Tables 34 and 35. These latter tables could be made somewhat simpler than they are, but, in the volumetric method, it is better to reduce all values to the temperature of the feed-water (or tail-water, which is at the same temperature as the head-water, within the limits of ordinary accuracy), so as to make the calculations consistent in appearance as well as in fact.

TABLE 41.—Illustrating the Advantages of the Method of Weighing Samples.

(The data have been computed from those of Tables 34 and 35 so as to represent closely the necessary data and calculations by the method of weights, Section 10, as applied to the calibration of the iron pipette, or calibrator, November 25th, 1914. All items marked *D* in the last column are parts of the data; all others result from computation. It will be seen that the temperature does not enter until it becomes necessary to pass to volumes.)

Explanation.	Line No.	Symbol.		Data.
Weight of salt solution taken for dilution with distilled water at temperature of laboratory, which temperature is not required	1	.....	11.7 grammes.	*D*
This salt solution is diluted with distilled water until the weight of the solution is	2	.....	1 000 grammes	*D*
Weight of dilution taken for titration	3	.....	10 grammes.	*D*
Mean titration of above samples	4	t	53.212 c. c.	*D*
Mean titration per kilogramme = 100 000 × Line 4 ÷ Line 1	5	v	454 800 c. c.	
Mean titration per 10-gramme sample of mixture from tank calibrator	6	t_2	53.273 c. c.	*D*
Mean titration per kilogramme of tail-water	7	v_2	5 327.3 c. c.

Ratio of dilution for special dilutions $[(W'_1 + w') \div w']$	15	F'	86.0	
Value of $(F' - 1)\, y = 85\, y$	16	$(F' - 1)\, y$	0.00199	
Value of the ratio of dilution in calibrator (by weights) found by dividing value of Line 15 by 1 + 0.00199 = F	17	F	85.829	
Weight of salt solution introduced into calibrator, which was then nearly full of normal canal water, and immediately afterward filled completely with normal canal water, the whole being agitated until the mixture was uniform	18	w	2.8137 kg.	*D*
W_2 = total weight of mixture in calibrator	19	$w\,F$	241.50	
Density of mixture at 4° cent.	20	d_2	1.0019	*D*
Volume at 4° cent. = $W_2 \div d_2$	21	Q_2	241.04	

It will be at once apparent that if it was the weight of the solution in the calibrator which was required, the calculations of Table 41 would be entirely independent of temperature observations, and therefore independent of temperature corrections. In the case of turbine tests, the only observation requiring a volumetric observation would be the determination of the weight of salt solution introduced into the head-water. This would probably best be done by observing the volume of salt solution consumed, exactly as was done during the tests described, with accurate weighings of standard volumes taken as samples from the sampling cocks in the 3-in. salt-solution supply pipe. These should be quickly measured and weighed on the spot and then poured back into the salt-solution tank. Several of these weighings should be made during the test, and the results should check well within the limit of permissible error. The mean of the results divided by the standard volume will be the density by which the total volume, or volume per second, is to be multiplied in order to get the total weight of solution consumed, or the weight per second, as the case may be.

The calculations of Table 41 are based on the last of Equations (27), Section 13, and the data have been reduced from those of Tables 34 and 35 by using Equations (38), Section 18.

79.—*Error 16.—Determination of Acting Head.*—It is the opinion of the writer that the determinations of acting head were the most doubtful of the data taken during the tests. The elevations of head- and tail-water could be determined quite accurately according to the requirements of the contract, but the real question at issue is as to the constant error involved in this method; and this leads to the more general question: How should head be measured for the purpose of turbine tests?

If one wishes to determine the energy actually entering the waterway for the turbine to be tested, it will be necessary to determine the actual kinetic energy of the water and the actual mean elevation of the water surface. If one wishes to determine the actual hydraulic efficiency of the installation—charging the wheel with the energy entering the waterway and deducting the energy which leaves the draft-tube—similar quantities for the tail-water must be determined. It would appear, however, that the latter operation should not be im-

posed by the terms of efficiency contracts, as it is urgently demanded that as little loss as possible result from tail-race flow.

Probably the contract should charge the turbine with all the energy flowing into the head-water passages and credit it with only such energy as it delivers at its shaft coupling. Contract efficiency and hydraulic efficiency, in the sense used here, are two entirely different things.

Now, it is highly probable that a sufficiently close estimate of the kinetic energy of the entering water can be computed from our practical knowledge of the character of flow of water in head-races, thereby avoiding the necessity for intricate current-meter or Pitot-tube surveys of water flow in such water passages.

Take, for example, the case of a head-race of width, $W = 2R$, when the water is flowing with parabolic distribution of velocities, looked on in plan, the axis of the parabola coinciding with the axis of the race. The total kinetic energy in the race would then be

$$E = \tfrac{1}{2}\int v^2\, dm = \frac{\gamma\, b}{2\, g}\int_{-R}^{+R}\left(V - \frac{y^2}{4\, a}\right)^3 dy = \frac{16}{35}\,\frac{\gamma\, b\, R\, V^3}{g}. \quad (143)$$

where $y^2 = 4\, ax$, $R^2 = 4\, aV$, $v = V - x$, $dm = \dfrac{\gamma\, v\, dA}{g}$, and $dA = b\, dy$, according to usual notation, $b\, W = A$ being the area of the cross-section of the race, b being the depth of water in the race, γ = specific weight of water, g = acceleration of gravity, and V being the maximum velocity in the section along its axis.

By a well-known property of the parabola, the mean velocity, V_m, in this problem, must be two-thirds of the maximum velocity, that is, $\frac{2}{3}\, V = V_m$. Hence, the discharge, Q, is equal to $A\, V_m$, the weight of the discharge is $\gamma\, A\, V_m$, and the total energy is

$$E = \frac{54}{35}\,\frac{\gamma\, b\, R\, V_m^3}{g} = \frac{27}{35}\,\frac{\gamma\, A\, V_m^3}{g}.$$

Consequently, as the mean velocity head is equal to the total energy divided by the weight of the discharge, we must have

$$\left.\begin{array}{l}\text{Mean velocity head for parabolic distribution in horizontal planes}\end{array}\right\} = \frac{54}{35}\,\frac{V_m^2}{2\, g} = 1.54\,\frac{V_m^2}{2\, g}. \quad (144)$$

It is quite apparent, therefore, that for anything like ordinary distribution of velocities, the mean velocity head is greater than the head due to the mean velocity in the raceway.

If we take the case of paraboloidal distribution in a circular race, it may be shown that

$$\left.\begin{array}{l}\text{Mean velocity head for paraboloidal}\\ \text{distribution in circular races run-}\\ \text{ning full}\end{array}\right\} = 2\,\frac{V_m^2}{2\,g} \quad \ldots\ldots (145)$$

The case of triangular distribution in horizontal planes in a rectangular race is identical with paraboloidal distribution in circular races running full, in so far as the relation between mean velocity head and head of mean velocity is concerned, that is, in either case the mean velocity head is twice the head due to the mean velocity.

At first sight, these last results do not seem to agree with parabolic distribution, in that the latter would appear to have relatively more high velocities than triangular distribution, and the numerator of mean velocity head is made up of cubes of the elementary velocities while the denominator contains first powers only. Apparently, the coefficient should be higher for parabolic than for paraboloidal or triangular distribution. The deception lies in the fact that V_m is greater relatively to V in parabolic distribution than it is in the other cases. Thus the actual mean velocity heads for a given maximum velocity, V, in the two cases are:

$$\left.\begin{array}{ll}\text{Parabolic distribution} & = 0.686\,\dfrac{V^2}{2\,g}\\ \text{Paraboloidal or triangular distribution} & = 0.50\,\dfrac{V^2}{2\,g}\end{array}\right\} \quad \ldots (146)$$

Thus, for a given maximum velocity, the mean velocity head is greater for parabolic than for paraboloidal or triangular flow, and the converse is true for a given mean velocity.

80.—Actual Distribution of Velocities in Raceways.—The foregoing assumptions are not sufficiently exact to represent accurately the actual conditions of flow in raceways. It is much more likely that the flow would approximate the conditions which may be indicated by adding a constant velocity, V_1, to the velocities of parabolic distribution in horizontal planes. Thus, if $S = V + V_1$ be substituted for V in the foregoing integral, Equation (143), V_1 being constant,

$$E = \frac{1}{2}\int v^2\,d\,m = 2\,\frac{\gamma\ b\ \sqrt{a}}{g}\int_0^V (S-x)^3\,d\,(x^{\frac{1}{2}})$$

therefore,

$$E = \frac{2\,\gamma\,b\,\sqrt{a}}{g}\left(k^3 - k^2 + \frac{3}{5}k - \frac{1}{7}\right)V^{\frac{7}{2}} \quad \ldots\ldots(147)$$

where $k = S \div V = (V + V_1) \div V$ and $y^2 = 4\,ax$.

By noting that $2\,\sqrt{a}\,V^{\frac{1}{2}} = R$, and $2\,R = W$, Equation (147) may be written

$$E = \frac{\gamma\,b\,W\,V^3}{2\,g}\left(k^3 - k^2 + \frac{3}{5}\,k - \frac{1}{7}\right) \quad \ldots\ldots(148)$$

Moreover, if V_m is the mean velocity in the raceway,

$$V_m = \frac{2}{3}V + V_1 = S - \frac{V}{3} = \left(k - \frac{1}{3}\right)V \quad \ldots\ldots(149)$$

and the discharge is

$$Q = b\,W\,V_m = \left(k - \frac{1}{3}\right)b\,W\,V \quad \ldots\ldots(150)$$

from which the mean velocity head is evidently

$$\frac{E}{Q\,\gamma} = \frac{\left(k^3 - k^2 + \frac{3}{5}k - \frac{1}{7}\right)}{\left(k - \frac{1}{3}\right)}\,\frac{V^2}{2\,g} \quad \ldots\ldots(151)$$

But, from Equation (149),

$$V^2 = \frac{V_m^2}{\left(k - \frac{1}{3}\right)^2} \quad \ldots\ldots(152)$$

so that, in terms of V_m, mean velocity head

$$= \frac{k^3 - k^2 + \frac{3}{5}\,k - \frac{1}{7}}{\left(k - \frac{1}{3}\right)^3}\,\frac{V_m^2}{2\,g} \quad \ldots\ldots(153)$$

This equation will approximate more or less closely the actual mean velocity head when the value of k approximates the actual value, based on the observed ratio of S to V.

Take, for example, the actual distribution in the tail-races observed by the writer in 1911.* In the first of these two tables, $S \div V = \frac{306}{306 - 150} = 1.96$. In the second, $S \div V = \frac{311}{145} = 2.14$,

* *Transactions*, Am. Soc. C. E., Vol. LXXVI, pp. 827-828, Tables 3 and 4.

the mean being 2.05, or approximately 2. Again, in Test *G*, of the present turbine tests, the corrected current-meter observations furnish the distribution shown in Table 42.

TABLE 42.—VELOCITIES AT ONE HUNDRED UNIFORMLY DISTRIBUTED METER POINTS IN HEAD-RACE OF UNIT NO. 13, TEST *G*.

(The unit is $\frac{1}{100}$ ft. per sec., except in the final averages, where it is 1 ft. per sec.)

Depths.	Velocities.									
1	260	261	286	256	261	259	257	286	317	351

	2 919	2 729	2 729	2 581	2 522	2 480	2 666	2 842	3 006	2 619

Total.....270.93

V_m = mean velocity = 2.7093.

V^2_m = 19.8871, say, 19.89.

In this distribution there are two extremely low velocities which probably should be neglected. Perhaps a velocity of 2 would be a fair minimum, so that $k = 366 \div (3.66 - 2) = 2.2$. It might be assumed, therefore, that:

In tail-races of 1911 tests, $k = 2.0$;
In head-races of 1914 tests, $k = 2.2$;

the corresponding values of the mean velocity head, by Equation (153), being:

$$\left.\begin{aligned} &\text{Mean velocity head in tail-race, tests of 1911.....} \\ &\text{Mean velocity head in head-race, tests of 1914.....} \end{aligned}\right\} \begin{aligned} &= \frac{4\,779}{4\,375}\frac{V^2_m}{2g} = 1.09\,\frac{V^2_m}{2g} \\ &= \frac{699}{655}\frac{V^2_m}{2g} = 1.07\,\frac{V^2_m}{2g} \end{aligned} \Bigg\} \quad ..(154)$$

Consequently, it may be said that the mean velocity head in the tail-races, down stream from the stilling racks, in the tests of 1911,

on a horizontal unit driven by a string of six turbines, was nearly the same relative to the head due to mean velocity as in the head-races, up stream from the trash racks, in the tests of 1914, on a vertical double-runner unit discharging nearly as much water as the turbine unit on the former occasion.

In the case where the maximum is about twice the minimum velocity in a raceway, it may be said, therefore, that, as an average,

$$\left.\begin{array}{l}\text{Mean velocity head, where } k = 2 \text{ and} \\ V_m = \text{mean velocity in raceway} \ldots\end{array}\right\} = 1.09\,\frac{V^2{}_m}{2\,g} \ldots . (155)$$

81.—Mean Velocity Head During the Tests.—We are now in a position to compute the actual mean velocity head in the head-races during any of the tests. The elevation of the floor of the head-race was 176 ft. above sea level. In Test *G* the water surface was at Elevation 199, the depth, therefore, being 23 ft. The width of the race is about 27 ft., so that the area of section was about 621 sq. ft. The discharge for this test was about 1 662 cu. ft. per sec., which corresponds to a mean velocity of 1 662 ÷ 621 = 2.68 ft. per sec. The head due to this velocity is 0.112 ft., which makes the mean velocity head = 0.12 ft.

Test 41 was taken very near the point of maximum efficiency. The discharge was 1 520 cu. ft. per sec., the elevation of the head-water was 196.7, the depth, consequently, was 20.7 and the area 560 sq. ft. Thus, the head due to the mean velocity was 0.115 ft., and the mean velocity head, by Equation (155), was 0.125 ft.

In some of the tests the elevation of the head-water was observed at the crown of the arch, at the point where the water changes its flow to descend to the wheel. At this point the water piled up, by reason of the change in direction, the surface water thereby coming very nearly to rest. Theoretically, this should equal the velocity head of the water before it is retarded. Table 43 gives the results of such observations as were made during the tests; and it will be seen that the rise of water due to its stoppage approximates closely the rise computed by the equations of the foregoing theoretical and practical study deduced in another way.

82.—Actual Mean Velocity Head.—Regardless of all theory, one may observe the individual velocities at the various points in a cross-section, and compute the velocity head at each point, thus enabling a

determination of the mean velocity head from direct calculations. This procedure would be indicated by the following equation, which is self-explanatory:

$$\left.\begin{aligned}\text{Mean velocity head in raceway, where } V_m \\ = \text{the mean velocity}\end{aligned}\right\} = \frac{E}{\gamma Q} = \frac{\frac{\gamma}{2g}\Sigma v^2 d Q}{\gamma Q} = \frac{1}{2g}\frac{\Sigma v^3 d A}{A V_m} = \frac{\frac{d A}{A}\Sigma v^3}{V^3_m}\frac{V^2_m}{2g} \quad \ldots (156)$$

In words, the theorem runs:

The ratio of the mean velocity head of flowing water to the head due to its mean velocity is equal to the ratio of the mean of the cubes of the velocities in the cross-section to the cube of the mean velocity.

Therefore,

$$\frac{k^3 - k^2 + \frac{3}{5}k - \frac{1}{7}}{\left(k - \frac{1}{3}\right)^3} = \frac{\frac{d A}{A}\Sigma v^3}{V^3_m} \quad \ldots (157)$$

for the distribution of velocities considered in Section 80.

TABLE 43.—Differences in Elevation Between Moving and Still Water in Head-Races Observed During Certain of the Tests on Units Nos. 11 and 12.

(The unit is 1 ft.)

121	195.12	195.00	0.12	210	195.97	195.82	0.15
122	195.78	195.67	0.11	211	196.52	196.34	0.18
				212	194.94	194.86	0.08

when the vertical projection of the velocities on a horizontal plane may be represented by a rectangle capped by a segment of a parabola, the velocities themselves being supposed to be horizontal and equal in any vertical, and k being the ratio of the combined height of the rectangle and segment (maximum velocity) to the height of the segment.

Applying Equation (156) to the cases of the tests of 1911 and 1914, by computing the mean of the cubes of the velocities in the tables and dividing by the cube of the mean velocities, the following may be determined as the actual coefficients for the head due to mean velocity:

$$\left.\begin{aligned} \text{Tests of 1911, coefficient} &= \frac{14.5}{13.5} = 1.07 \\ \text{“ “ 1914, “ “} &= \frac{21.30}{19.89} = 1.07 \end{aligned}\right\} \quad \ldots\ldots (158)$$

The values agree very closely with those deduced above, based on less direct assumptions. The general conclusion is that Equation (157) gives the value of the coefficient in terms of k with a considerable degree of precision, where the flow is not unusual in character.

83.—Personal Errors and Carelessness.—Shaking Flasks.—It requires experience for a person to develop what is technically called a personal error. Such an error is a systematic error in that it always occurs in the same sense and in about the same degree under given circumstances. In many cases this error may be eliminated by properly arranging the methods of observing. For example, if a chemist has acquired by experience the fixed habit of reading a burette in such a manner that all observations are too high by 0.02 c.c., then the error is eliminated when he subtracts the lower from the higher reading to determine the number of cubic centimeters of silver nitrate consumed in a titration. Hence, if it requires two gauge readers to determine the acting head during a turbine test, it would be advisable to have them change stations during the test, so as to have equal numbers of head and tail-gauge readings by each observer. Again, in the case of pipettings, two chemists may handle their instruments in different ways, so that pipettings by one of them will always be slightly larger than by the other. Such an error may be eliminated from discharge measurements by the method of group titrations, discussed in Section 48.

Carelessness, however, can be guarded against only by its prevention. Ignorance is closely akin to carelessness, and must be prevented

by having every observer understand exactly what he is to do and how it is to be done. The rules must be specific, pertinent, and concise. Therefore, the person who undertakes to conduct a chemical test must have every detail of it at his command. He must go over the ground thoroughly in advance, and provide for every contingency.

Nothing illustrates the importance of these remarks better than the difficulties encountered in securing accurate chemical work during the first few of the turbine tests described herein. It was apparent that something was radically wrong. After the first week's work, the writer devoted an entire day in the laboratory to repeating some work which was manifestly in error, the result being the discovery that the dilutions were not being thoroughly mixed by sufficient agitation of the flasks containing them.

All chemists know that flasks must be shaken in order to secure perfect mixtures, but it does not seem that there is any definite rule as to how many times, or how vigorously, the shaking must be administered. It would seem that this should depend on the shape and size of the receptacle in which the mixture is to be effected and the manner of shaking.

In the case of an ordinary stoppered liter flask with a long neck, about 0.6 in. in diameter, it requires from 25 to 30 double shakes or inversions, with time for the air to rise to the surface of the liquid in each position, in order to secure the uniform mixture of 10 c.c. of nearly saturated salt solution with about 990 c.c. of distilled water. In order to insure results, the rule was adopted that such operations should require 40 double inversions, with sufficient time allowance in each position for the air to rise to the surface. In the case of a different size or shape, the rule will probably require modification.

The calibrations of the flasks are given in diagrammatic form in Fig. 6.

84.—Effect of Variations in Discharge on the Concentration of Tail-Water Samples.—The discharge of a turbine is likely to vary, even when efforts are made to maintain uniform conditions during a test. It is necessary, therefore, to show that the method of testing and sampling does not introduce an error.

First, it is necessary to show that, when a tail-race sample is pumped into a sample bottle at a uniform rate, the resulting concentration is the time-average concentration of the water at the sampling pipe, in-

stead of the mean concentration relative to all the volume of the water passing the pipe.

The time-average concentration is evidently

$$\int \frac{c_2\, d\, t}{T} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (159)$$

and the total quantity of salt in the sample is

$$\int c_2\, x\, d\, t \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (160)$$

where x is the rate at which the sample is pumped into the sample bottle, which rate is supposed to be constant. The total volume of the sample is

$$\int x\, d\, t \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (161)$$

CURVES SHOWING VOLUMES OF FLASKS AT VARIOUS TEMPERATURES,

As Derived from Direct Volumetric Comparisons with the Contents of Flask No. 1456 or Flask No. 11, which were Calibrated by the U.S. Bureau of Standards.

Note:-Flask No. 1456 was calibrated by Arthur Schweier at the Chemical Laboratory of the University of Pittsburgh, and its Contents at 19.7°C. were found to be 1002.68 c.c., as compared with 1003.00 c.c. given by the U.S.B.S.

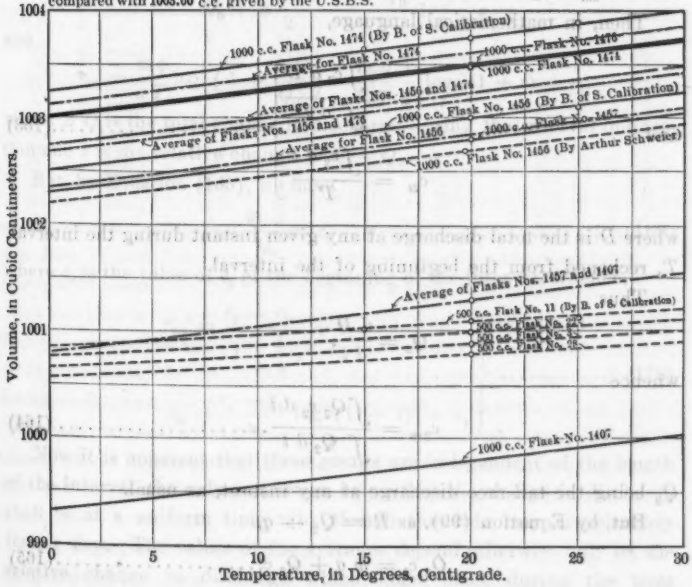

FIG. 6.

Therefore, the concentration of the sample is

$$c_2 = \frac{\int c_2 x\, d\, t}{\int x\, d\, t} = \frac{\int c_2\, d\, t}{T} \quad \ldots\ldots\ldots\ldots\ldots\ldots (162)$$

as x is constant.

By Equation (159), however, this is a time average. Hence, the proposition is proved that the concentrations of samples pumped at uniform rates are time averages.

We may now investigate the relations existing between time averages and volume averages, with especial reference to tail-water concentrations.

Let c_{2m} be the average concentration with reference to the total volume of discharge during a given time, T, which is supposed to be an interval during which the discharge, Q_2, varies, and which is included as part of the time of a test. Let c_{2t} be the time average of the concentration during the same period. The object is to find the relation of c_{2m} to c_{2t}.

Then, in mathematical language,

$$\left.\begin{aligned} c_{2m} &= \frac{\int c_2\, d\, D}{\int d\, D} \\ \text{and} \qquad c_{2t} &= \frac{\int c_2\, d\, t}{T} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (163)$$

where D is the total discharge at any given instant during the interval, T, reckoned from the beginning of the interval.

Thus

$$Q_2 = \frac{d\, D}{d\, t},$$

whence

$$c_{2m} = \frac{\int Q_2\, c_2\, d\, t}{\int Q_2\, d\, t} \quad \ldots\ldots\ldots\ldots\ldots\ldots (164)$$

Q_2 being the tail-race discharge at any instant, as usual.

But, by Equation (99), as $R = Q_2 \div q$,

$$Q_2\, c_2 = m\, q + Q_2\, c_1 \quad \ldots\ldots\ldots\ldots\ldots\ldots (165)$$

where $m = c - k\, c_1$.

Therefore, by Equations (162), (163), and (164),

$$\left.\begin{aligned} c_{2m} &= \frac{\int (m\,q + Q_2\,c_1)\,d\,t}{\int Q_2\,d\,t} = \frac{m\,q\,T}{\int Q_2\,d\,t} + c_1 \\ c_{2t} &= \frac{\int \frac{m\,q + Q_2\,c_1}{Q_2}\,d\,t}{T} = m\,q \int \frac{d\,t}{Q_2} + c_1 \end{aligned}\right\} \quad \ldots\ldots (166)$$

From the nature of the integrals, it is apparent that the discrepancy between c_{2m} and c_{2t} depends on the manner in which the discharge varies during the interval over which the averages are to be computed. Suppose, for example, that

$$Q_2 = Q_0 + a\,t \quad \ldots\ldots (167)$$

where a is constant and Q_0 is the discharge at the beginning of the interval, t being the time reckoned from that instant.

Then we may show that

$$c_{2m} = \frac{m\,q}{Q_0 + a\,\frac{T}{2}} + c_1 = \frac{m\,q}{Q_0}\,\frac{1}{1 + \frac{1}{2}\,z} + c_1 \quad \ldots\ldots (168)$$

and

$$c_{2t} = \frac{m\,q}{a\,T} \log.\left(1 + \frac{\Delta\,Q}{Q_0}\right) = \frac{m\,q}{Q_0}\,\frac{1}{z} \log.\,(1 + z) + c_1$$

where $\Delta\,Q$ is the total change in discharge during the interval in question and z is the relative change, $\Delta\,Q \div Q_0$.

But, by Equation (165), we have

$$\frac{m\,q}{Q_0} = c_0 - c_1 \quad \ldots\ldots (169)$$

where c_0 is the value of c_2 at the beginning of the interval, whence,

$$\left.\begin{aligned} c_{2m} &= \frac{c_0 - c_1}{1 + \frac{1}{2}\,z} + c_1 \\ c_{2t} &= \frac{c_0 - c_1}{z} \log.\,(1 + z) + c_1 \end{aligned}\right\} \quad \ldots\ldots (170)$$

Now it is apparent that these results are independent of the length of the interval, the only restriction being that the change in discharge shall be at a uniform time rate, though this rate may be relatively fast or slow. The values of the averages depend otherwise only on the relative change in discharge which takes place during the time considered.

Let it be supposed, therefore, that the relative changes of discharge are, respectively, 0.1, 0.2, 0.3, 0.4, and 0.5, first in the sense of increase and then the reverse. The resulting comparisons of the values of v_{2m} and v_{2t} are given in Table 44, together with the calculations.

TABLE 44.—CALCULATION OF THE RATIOS OF THE TIME AVERAGE CONCENTRATIONS IN THE TAIL-RACE TO THE CORRESPONDING MEAN CONCENTRATIONS FOR ANY INTERVAL OF TIME DURING WHICH THE DISCHARGE INCREASES OR DECREASES AT A UNIFORM RATE EXPRESSED AS A FUNCTION OF THE RELATIVE CHANGE IN DISCHARGE DURING THE INTERVAL. THE CONCENTRATION OF THE TAIL-WATER AT THE BEGINNING OF THE INTERVAL IS ASSUMED TO BE THE EQUIVALENT OF 110 C.C. OF SILVER NITRATE TITRATION PER LITER, AND THE NORMAL HEAD-WATER CONCENTRATION 25 C.C.

(Thus $v_0 - v_1 = 85$ c.c.)

z	$\frac{1}{z}\log.(1+z)$	$\frac{1}{1+\frac{1}{2}z}$	v_{2t} c.c.	v_{2m} c.c.	$v_{2t} - v_{2m}$ c.c.	$\frac{v_{2t}}{v_{2m}}$	Percentage of error.
0.5	0.8109	0.8000	93.93	93.00	0.93	1.0100	1.0
0.4	0.8412	0.8333	96.50	95.83	0.67	1.0070	0.70
0.3	0.8745	0.8696	99.33	98.92	0.41	1.0041	0.41
0.2	0.9116	0.9091	102.49	102.27	0.22	1.0022	0.22
0.1	0.9531	0.9524	106.01	105.95	0.06	1.0006	0.06
0.05	0.9758	0.9756	107.94	107.93	0.01	1.0001	0.01
0.00	1.0000	1.0000	110.00	110.00	0.00	1.0000	0.00
−0.05	1.0258	1.0256	112.19	112.18	0.01	1.0001	0.01
−0.1	1.0540	1.0526	114.59	114.47	0.12	1.0008	0.08
−0.2	1.1155	1.1111	119.82	119.44	0.38	1.0032	0.32
−0.3	1.1890	1.1765	126.06	125.00	1.06	1.0085	0.85
−0.4	1.2770	1.2500	133.55	131.25	2.30	1.0175	1.75
−0.5	1.3862	1.3333	142.83	138.33	4.50	1.0325	3.25

It is very evident from the array of figures in Table 44 that any change in discharge during a test causes an over-estimate of concentration of tail-water where the samples are taken at a uniform rate, but that the error introduced is less than 0.1% for variations as great as 10% of the discharge, and less than 0.01% for variations less than 5% of the discharge. Moreover, these errors will be greatly diminished when the power is constant during a part of the test, so that they are entirely negligible in the tests now being examined, as the maximum variation of power during any of the decisive tests was less than 5 per cent.

The general truth, that time averages of concentrations for variable discharges with uniform dosing are too large as compared to volume averages, may be seen without recourse to computations.

First, suppose the discharge to increase during a certain interval of time. Then the concentration must decrease during that interval. Now, a time average gives equal weights to the momentary concentrations at all instants, and a volume average, in this case, gives greater weight to the momentary concentrations as time progresses. Therefore, for increasing discharge, the volume average gives greater weights to the weaker concentrations and results in a smaller value than does a time average.

Second, suppose the discharge to decrease during a certain interval of time. Then the concentration must increase during that interval; but the time average gives equal weights to the momentary concentrations at all instants, and a volume average, in this case, gives less weight to the momentary concentrations as time progresses. Therefore, for decreasing discharge, the volume average gives smaller weights to the stronger concentrations, and results in a smaller value than does a time average.

Therefore, for variable discharges, with uniform dosing, the time average is always greater than the volume-average concentration.

This truth may be seen very clearly in still another manner. Suppose two tail-water samples are being accumulated in two sample bottles, the first being pumped into its bottle at a uniform rate while the second is pumped into its bottle at a rate proportional to the discharge, both samples being started at the same rate.

Then, if the discharge is increasing, it is clear that the first bottle is not receiving enough of the weaker solutions as time progresses; but, if the discharge is decreasing, it is clear that the first bottle is receiving too much of the stronger solutions as time progresses.

It follows, in either case, that the concentration is greater in the first than in the second sample bottle.

85.—Securing Volume Average Concentrations.—In determining on the method of sampling with small pumps drawing their supply from suctions in the tail-race, it was realized that time averages of concentration would result, rather than volume averages; but it was thought that it would be better to have something which was definite than to try to secure a volume average in the absence of any method for pumping, or otherwise taking, samples from the tail-race at rates which varied in direct proportion to the velocity of the tail-water at the inlet of suctions.

In considering the various methods of taking continuous samples, both the vacuum and gravity methods were discussed. The power-house was equipped with a vacuum system, the vacuum being derived from one or more of the draft-tubes. The samples might have been sucked up by this vacuum and tapped off at various points by a simple device. An inverted caisson might have been constructed and pumped out, or the sump well in the power-house might have been used, in either of which a system of pipes discharging the samples continuously by gravity into the sample bottles could have been installed.

It was thought, however, that the small pumps would be more reliable as to the constancy of rate than either of these methods, and they were therefore adopted.

If it is desired to secure volume-average samples, both as to time and place, in the tail-race, the object may be accomplished by installing the suctions of the pumps in the form of Pitot tubes with static orifices attached, the Pitot tubes pointing up stream with their axes parallel to the center line of the race.

Both the Pitot tubes and static orifices must be connected by small tubes leading from holes in their walls to the static and dynamic gauges arranged alongside the corresponding pumps, or other devices for drawing out the samples.

An attendant regulates the rate of sampling at each pump or sampling device, so that the dynamic and static columns, which are drawn up in the usual manner on the graduated scales corresponding to any pump, register the same elevation.

If this condition is maintained with reasonable exactness during a test, the concentration of each sample will be a volume average for that sample during the test.

If the relative volumes of the samples which have been taken in this manner are used as weights for the corresponding samples, the weighted mean of all the samples will be the volume-average concentration for the test as a whole.

Finally, if all the samples thus taken are thoroughly mixed in one receptacle, or if given fractions of each of the samples are thus mixed, the concentration of the mixture will be the volume-average concentration for the test.

It may be added that similar procedure will serve for the method of weights, as against the method of volumes.

86.—Comparison of Discharges by the Method of Special Dilutions with Those Simultaneously Determined by the Method of Unbalanced Evaporations.—In these studies it has been the endeavor to develop a method which will eliminate as far as possible all the errors of the chemistry, as well as to discover the corrections to be applied in the chemistry, where the method of unbalanced evaporations has been used.

Unbalanced evaporations result in the methods connected with such equations as (14), (17), (46), (53), (98), and (99). The corrections have been discussed in Section 43, *et seq.* The method of special dilutions applies particularly to such equations as (27), (28), (39), (44), (45), (56), (106), (107), and (108). It will strengthen the confidence in the method of correcting the errors for unbalanced evaporations and in the method of special dilutions, or balanced evaporations, if the results by these two methods agree.

In order to facilitate the comparison, Table 45 has been prepared. This not only enables a direct comparison in the individual tests, but also enables the direct comparison of the aggregates of discharge for all the tests on each unit, and all the tests collectively.

TABLE 45.—Comparison of Discharges Obtained by the Method of Special Dilutions with Those by the Method of Unbalanced Evaporations.

Unit No. 11.			Unit No. 12.			Unit No. 13.		
Test No.	Discharge by special dilution.	Discharge by unbalanced evaporation.	Test No.	Discharge by special dilution.	Discharge by unbalanced evaporation.	Test No.	Discharge by special dilution.	Discharge by unbalanced evaporation.
105	1 443.4	1 448.8	200	1 564.5	1 571.0	23 *B*	1 398.9	1 421.8
106	1 539.0	1 538.5	201	1 515.7	1 515.0	26 *B*	1 497.4	1 474.1
107	1 519.4	1 518.9	202	1 481.1	1 470.1			
108	1 487.7	1 475.8	203	1 517.8	1 520.6			
109	1 492.0	1 482.4	204	1 505.3	1 505.0			
			205	1 512.2	1 511.0			
			206	1 491.4	1 493.5			
			207	1 485.4	1 488.0			
			208	1 501.8	1 496.2			
			209	1 560.0	1 561.7			
			210	1 539.4	1 543.2			
			211	1 544.1	1 545.9			
			212	1 489.4	1 492.9			
Sub-totals.	7 481.5	7 464.4	.....	19 708.1	19 714.1	.....	2 896.3	2 895.9

The aggregate discharge may be summarized as follows:

AGGREGATE DISCHARGE.

Unit No.	Special dilutions.	Unbalanced evaporations.
11	7 481.5	7 464.4
12	19 708.1	19 714.1
13	2 896.3	2 895.9
Totals.....	30 085.9	30 074.4

The tests which are compared for Unit No. 11 were the first five which were run on this unit, and they were not so good as the later tests. No unbalanced evaporations, however, were made in the later tests, so that only five tests are available for the purpose of comparison. The discrepancy between the results by the two methods, nevertheless, is only 17.1 cu. ft. per sec. in about 7 500, or about $\frac{1}{4}$ of 1%, for the tests on Unit No. 11.

If the tests on Units Nos. 12 and 13 are compared collectively, the result is as follows:

AGGREGATE DISCHARGES OF UNITS NOS. 12 AND 13.

Special Dilutions.	Unbalanced Evaporations.
22 604.4	22 610.0

The difference is 6.4 cu. ft. per sec. in about 23 000, or a discrepancy of less than 0.03 per cent. In the case of the aggregates for all the tests, where both methods were used, the discrepancy is only slightly more than 0.03 per cent.

It may be concluded, therefore, that the method of correcting titrations in the case of unbalanced evaporations and the method of special dilutions are theoretically and practically correct.

87.—Determination of Size of Solution Tank, Sizes of Samples, and Strength of Silver Nitrate Solution.—In laying out a series of tests, it will be convenient to have simple formulas embracing the relations of titrations, volumes, and sizes of samples. As a general rule, it will be on the side of economy, as regards the capacity of the solution tank, to have the strength of the dosing solution as great as practicable. It was found quite satisfactory to have a salt solution of 300 grammes per liter, but as any increase in strength above this value adds considerably to the difficulty of dissolving the additional quantity of salt

required, it will generally be best to adhere to 300 grammes per liter, or less, as the occasion may seem to indicate.

As regards the concentration of the silver nitrate, it should be observed that the stronger this solution the more salt it will require to create a given titration on a sample of given size. Therefore, for economy of salt, it will be desirable to keep the nitrate solution as weak as consistent with definiteness of end points.

It follows from these remarks that computations involving the concentrations of the salt solution and silver nitrate should always have regard to the possible and practicable values of these quantities. The quantities which enter the equations are so related that there will be found a great variety of ways in which the tests may be planned, and this will be found very satisfactory, as it is rare that two series of tests on different installations will demand the same treatment.

Let e = salt equivalent of 1 gramme of silver nitrate = 0.344;

c = concentration of salt solution;

c_s = concentration of silver nitrate solution;

ρ = ratio of dilution of salt solution with distilled water;

t_1 = titration of a sample of normal head-water;

t_2 = titration of a sample of tail-water or special dilution;

V = nominal volume of a sample for titration after evaporation, or of dilute salt solution as pipetted into its casserole, that is, $V = V_1 = V_2 = V'_2$;

ρ_2 = ratio of sample volume measured for evaporation to the nominal volume to which the evaporation is carried before the titration; this also applies to ρ'_2;

R = ratio of dilution anticipated in any test;

v = titration per liter of salt solution based on the titration of a sample of dilute salt solution of the volume, V;

t = actual titration of the sample of dilute salt solution of the volume, V;

S = measured volume of a sample of tail-water, special dilution, or computed volume of a sample of normal head-water; that is, $S = S_1 = S_2 = S'_2$.

Then, the following relations are obvious:

$$e = 0.3441 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (171)$$

$$v = \frac{1\,000\,c}{c_s\,e} = \frac{2\,906\,c}{c_s} \quad \ldots\ldots\ldots (v \text{ in cubic centimeters}) \ldots . (172)$$

Therefore, if c is the concentration of a sample of any kind, and t the titration, S being the volume of the sample, in liters, we have:

$$t = \frac{2\,906\,S\,c}{c_s} \quad \text{(general formula for titration)} \quad \ldots\ldots(173)$$

Again,

$$v = \frac{\rho\,t}{V} \quad \ldots\ldots(174)$$

so that

$$\frac{c}{c_s} = \frac{v}{2\,906} = \frac{\rho\,t}{2\,906\,V} = \frac{\rho\,\rho_2\,t}{2\,906\,S} \quad \ldots\ldots(175)$$

$$c_s = \frac{871\,800\,V}{\rho\,t} = \frac{871\,800\,S}{\rho\,\rho_2\,t} \quad (c = 300) \quad \ldots\ldots(176)$$

From Equations (99),

$$R = \frac{v - k\,v_1}{v_2 - v_1} \quad \ldots\ldots(177)$$

or

$$R = \frac{v}{v_2 - v_1} \quad \text{(approximately)} \quad \ldots\ldots(178)$$

as v_1 is supposed to be small, relatively to v. Thus:

$$R = \frac{\rho\,\frac{t}{V}}{\frac{t_2}{S_2} - \frac{t_1}{S_1}} \quad \text{(approximately)} \quad \ldots\ldots(179)$$

but $V = V_1 = V'_2$, $S = S_1 = S_2$, $t = t_2 = t'_2$, etc., so that

$$R = \frac{\rho\,\rho_2\,t}{t_2 - t_1} \quad \ldots\ldots(180)$$

or,

$$\rho\,\rho_2 = R\left(1 - \frac{t_1}{t_2}\right) \quad \ldots\ldots(181)$$

From this and an equation of the form of Equation (173),

$$\rho\,\rho_2 = R\left(1 - \frac{2\,906\,S_1\,c_1}{c_s\,t_2}\right) \quad \ldots\ldots(182)$$

or

$$c_s = \frac{2\,906\,S_1\,c_1}{t_2\left(1 - \frac{\rho\,\rho_2}{R}\right)} \quad \ldots\ldots(183)$$

which, when multiplied by Equation (175), gives

$$c = \frac{\rho\,\rho_2\,c_1}{1 - \frac{\rho\,\rho_2}{R}} = \frac{R\,c_1}{\frac{R}{\rho\,\rho_2} - 1} \quad \ldots\ldots(184)$$

The foregoing equations, of course, assume that the method of special dilutions, or balanced evaporations and titrations, is to be used.

No normal head-water is evaporated, but the planning of the tests requires that the properties of the normal head-water shall be taken into account, so that, in any case, a series of analyses of the head-water should be made to lead to an accurate balance of evaporations in the actual tests.

The value of c_1, therefore, will be known in advance, having been determined from analyses made under circumstances closely simulating an actual test, and the value of S_1 may be chosen equal to S_2 in the foregoing equations. It is not likely that c_1 will be so variable as to render a close balance of titrations impracticable. The object of the calculations will not be frustrated by considerable relative variations in c_1, when they do occur.

Let it be required, for example, to plan a series of tests where the discharge will vary from 1 000 to 1 500 cu. ft. per sec. It may be observed that the ratio of dilution, R, and therefore, R', can be closely the same in all the tests by varying the rate of discharge, q, of salt solution so as to maintain

$$\frac{Q}{q} = R \text{ constant} \ldots\ldots\ldots\ldots\ldots\ldots (185)$$

The values of $t_2 = t'_2 = t$, $S_2 = S'_2$, $V_2 = V'_2 = V$, and ρ, may be chosen arbitrarily, from which the values of c and c_s may be computed so as to satisfy all the requirements, it being merely necessary to see that c and c_s do not take on impractical values. When they do, a different choice of dimensions, capacities, titrations, or rates of dilution must be made, and repeated if necessary until satisfactory proportions are finally determined.

Therefore, let the data be taken as follows:

Evaporations are to be of ½-liter samples to 10 c.c. in a casserole for titration, or $S = \frac{1}{2}$, $V = 0.01$, and $\rho_2 = 50$.

Titrations are to be limited to values less than 50 c.c., say $t = t_2 = 47.50$ c.c.

Dilutions of salt solution are to be 10 c.c. salt solution to 1 liter in a liter flask, 10 c.c. of the resultant mixture to be taken in a casserole for titration, or $\rho = 100$.

The concentration of the normal head-water has been previously determined to be 0.0133, as computed from a preliminary test of several salt-solution samples and special dilutions of the sort to be used in the tests.

The ratio of dilution may be first tried at $R = 6\,500$.

Then from Equations (183) and (184), we have

$$c_2 = \frac{2\,906 \times 0.5 \times 0.0133}{(47.50)\left(1 - \frac{5\,000}{6\,500}\right)} = 1.76 \text{ grammes per liter} \quad \ldots\ldots (186)$$

$$c = \frac{6\,500 \times 0.0133}{\frac{6\,500}{5\,000} - 1} = 288.3 \text{ grammes per liter} \quad \ldots\ldots (187)$$

These concentrations, 1.76 grammes per liter for the silver nitrate and 288 grammes per liter for the salt solution, are good practical values, and satisfy the conditions. For a discharge of 1 500 cu. ft. per sec., the rate of discharge for salt solution must be

$$q = \frac{Q}{R} = \frac{1\,500}{6\,500} = 0.231 \text{ cu. ft. per sec} \quad \ldots\ldots (188)$$

which is a trifle more than 6.5 liters per sec.

The salt rate, therefore, is

$$288.3 \times 6.53 = 1.880 \text{ kg. per sec} \quad \ldots\ldots (189)$$

so that, if a test is to last for 15 min. with a margin of 10 min. before the start to secure steady conditions, there will be required

$$1.880 \times 60 \times 25 = 2\,825 \text{ kg. of salt per test} \quad \ldots\ldots (190)$$

which is equivalent to about 3.1 tons.

The total quantity of solution consumed per test would be $6.5 \times 1\,500 = 9\,800$ liters, or about 2 600 gal. This would probably demand a 3 000-gal. tank.

Now, the salt rate and rate of discharge of salt solution are, respectively,

$$\text{Salt rate} = q\,c = \frac{Q\,c}{R} = \frac{Q\,c_1}{\frac{R}{\rho\,\rho_2} - 1} \quad \ldots\ldots (191)$$

and

$$q = \frac{Q}{R} \quad \ldots\ldots (192)$$

It is clear, therefore, that the greater we take R, other things remaining the same, the less the salt requirement and the smaller the salt-solution equipment.

The value of R, however, is limited, to a large extent, by the degree of accuracy required in the test. In order to secure a given degree

of accuracy, for example, it will be necessary to introduce a certain quantity of salt into the head-race to secure a sufficiently large concentration. This will be required, as the titration must not be less than a certain quantity when there is a limit of permissible error.

Perhaps the following is a better procedure than that of the foregoing problem. Suppose the degree of accuracy requires that errors of 1 in 400 shall be easily appreciable. Then, as it is easy to detect 0.1 c.c. on the scale of a 75-c.c. burette, it may be required that sufficient salt, over and above that contained initially in the head-water, shall be introduced to require 40 c.c. of silver nitrate in the titration. The concentration of the salt solution will be 300 grammes per liter, and that of the silver nitrate will be 1.5 grammes per liter. The former is about as strong as it can be taken, and the latter is about as weak as practicable, according to the investigations of Dr. Mellet. The ratio of dilution, $R = R'$, is given by

$$R = 2\,906 \frac{c}{c_2} \frac{S}{t_2} \qquad (193)$$

where t_2 is not the titration of the tail-water, but is that part of it due to the introduction of salt. Thus, $t_2 = 40$ in this case. S is limited by the quantity which may be conveniently taken for evaporation, but should evidently be as large as this limit. A quantity of $\frac{1}{2}$ liter is about as large as most cases will admit. A liter makes a long evaporation and concentrates to a greater extent all the other impurities of the water along with the salt. However, when the method of special dilutions is used, it will be found that liter-evaporations, and even larger, will be possible when the discharge to be determined is very great.

Hence, with $\frac{1}{2}$-liter samples,

$$R = 2\,906 \times \frac{300}{1.5} \times \frac{0.5}{40} = 7\,265.$$

By Equation (184) we find

$$\rho = \frac{R}{\rho_2 \left(1 + R \frac{c_1}{c}\right)} \qquad (194)$$

which, for the foregoing determined value of R, and $\rho_2 = 50$, $V = 0.01$, $c_1 = 0.0133$, becomes

$$\rho = \frac{7\,265}{50\,(1 + 0.322)} = 109.7.$$

Thus we find that

$$1 - \frac{\rho_1 \rho_2}{R} = 1 - \frac{109.7 \times 50}{7\,265} = 0.245$$

and hence, by Equation (183),

$$t_2 = 2\,906 \frac{S}{\left(1 - \frac{\rho_1 \rho_2}{R}\right)} \frac{c_1}{c_s} \quad \ldots\ldots\ldots\ldots\ldots\ldots (195)$$

which, on substitution of values, gives $t_2 = 52.9$, and thus checks the value 12.9 of t_1, given by Equation (173), on addition of 40 to the latter.

The rate of discharge of the salt solution is

$$q = \frac{Q}{R} = \frac{1\,500}{7\,265} = 0.206 \text{ cu. ft. per sec.},$$

which is the equivalent of 5.8 liters per sec., when the discharge to be measured is 1 500 cu. ft. per sec.

The size of the salt-solution tank for a 15-min. test, with 10-min. discharge prior to the start to secure steady flow, is $25 \times 60 \times 5.8 =$ 8 700 liters, and this would require $8\,700 \times 0.300 = 2\,610$ kg. of salt, or about 2.9 tons of salt for each test.

In practice it would probably be better to take $R = 7\,225$, which is the square of 85, and $\rho = 110$. Thus the special dilutions can be quickly made with two 850-c.c. flasks and a 10-c.c. pipette; and the dilution with distilled water can be effected in a flask containing 1 100 c.c., the actual value of ρ having to be computed from the flask and pipette calibrations in any case where precision is to be exacted.

Figs. 7 and 8 will facilitate the determination of the relations between ratio of dilution, size of sample, and titration of the injected salt when the ratio, $c \div c_s$, of the concentration of the salt solution to that of the silver nitrate is 200, which corresponds to concentrations of 300 and 1.5, respectively.

*88.—Care of Samples, and Method for Taking and Treating.**— These operations are among the most important connected with the turbine tests. Consequently, the chemists engaged in this work must take the most scrupulous care to see that samples are properly taken, and not allowed to become contaminated before they are treated in the chemical laboratory.

* Sections 88 and 89 are copied from the original instructions to chemists, with slight modification. They pertain particularly to the method of measuring samples by volume.

FIG. 8.

Three classes of samples are taken during each test: The first is the salt solution sample, which is taken from the 3-in. supply pipe leading from the salt solution tank to the suction of the 8-in. centrifugal pump which feeds the twelve distributing pipes. The second is the sample of the normal canal water or normal head-water taken from the head-race before the water reaches the distributing pipes. The third is the sample of the tail-water after it has been dosed with the salt solution and after it has passed through the racks, turbines, and draft-tubes. These latter samples are taken from eighteen* small pumps which are in the chamber immediately above the draft-tubes of the turbine under test. It is imperative that a chemist be in charge of each of these three classes of samples. The chemist in charge of any one of these classes is to keep his sample bottles in view at all times from the time that he leaves the chemical laboratory until he returns thereto with the samples. The object of this is to prevent the possibility of the samples becoming affected in any way through the breakage of a bottle, the accidental introduction of extraneous substances or the accidental interchange of two different samples. In order to render this care easy and systematic, a number of carrier boxes, provided with compartments, have been made, and each compartment must be numbered so that the corresponding sample of the same number will always be placed in that particular compartment. In the same way the draining racks in the laboratory are to be numbered, and bottles containing the samples of the corresponding numbers are always to be drained in the rack carrying the particular number which pertains to that bottle. The openings on the water baths shall also be numbered in the same manner, so that the same sample is always evaporated on the same opening and supplied from the same separatory funnel in the funnel rack. In similar manner there shall be provided a table, in the immediate vicinity of the water baths, carrying squares corresponding in position to the openings in the water baths, and these squares shall be numbered in a similar manner to the openings on the water baths. In order still further to systematize the handling of these samples, it may be understood that odd numbers pertain to the west side of the head- and tail-races, and even numbers to the east side. It is a simple matter then to arrange the numbers in rows with the odd numbers representing the west side and the even numbers

* Originally there were only twelve regular tail-water samples.

the east side. The forms for recording observations shall be arranged diagrammatically to correspond to this system. After a complete set of samples has been taken during any test, the bottles are to be tightly corked and carried to the laboratory in charge of the particular chemist whose duty it is to care for the particular class of samples in question.

Normal Head-Water Samples.—The duty of the chemist who is in charge of the normal head-water samples shall be: first, to ascertain the length of the time of the test; second, to ascertain the positions from which normal head-water samples are desired; third, to record the time of beginning and the time of ceasing to take the normal head-water samples. These times shall be recorded by the chemist and turned in with his record of observations during the test. Ordinarily, one normal head-water sample will be taken from each of the four normal head-water sampling pumps during each test. Each sample is to contain approximately 1 gal. The odd-numbered samples shall be taken from the west sampling pipes, and the even-numbered samples from the east sampling pipes; and on every record the position and depth of the intake of the suction pipe on these sampling pumps during the test shall be noted by the chemist in charge of the particular samples in question. At the end of the test these samples are to be carried to the laboratory in the view of, and under the direction of, the chemist in charge. It is an absolute rule in taking these samples that every endeavor be made by all parties concerned to see that the sample fills into the proper sample bottle at as nearly a uniform rate as possible.

Tail-Water Samples.—The chemist in charge of the tail-water samples shall first ascertain the length of time of the test and the time of beginning. He shall then see that the tail-water sampling pumps are started in sufficient time to permit him to gauge the discharges, so that his gallon sample bottles will be nearly, though not quite, filled, during the test. He is then to proceed from the laboratory to the chamber immediately above the draft-tube of the turbine to be tested, where the sampling pumps are placed. The eighteen sample bottles are then to be placed on the movable boards provided for sliding the bottles under the proper sampling pipes. It shall also be the duty of this chemist, as in the case of all other chemists in charge of sampling bottles, to see in advance that each bottle is properly cleaned and prepared for receiving the sample. The greatest care should be taken to see that bottles are thoroughly rinsed with the dosed tail-water and

thoroughly drained before admitting the samples. He shall also keep the samples in his view at all times, so that there will be no possibility of contamination or interchange of samples by accident or otherwise. A few minutes before the beginning of a test, a long ring of the telephone bell will indicate to this sample man that the test is about to begin. A short time later three long rings of the bell will indicate the instant of beginning the test. The test shall begin at the instant when the third long ring begins. One minute after receiving this signal the levers controlling the parts which carry the sampling bottles shall be moved over into such a position that all the bottles will begin to receive their sample at that instant. A few minutes before the end of the test a long ring on the telephone bell will indicate that the test is about to end. Simultaneously at the beginning of the third of the three long rings which follow the preliminary long ring, the test shall be at an end, and 1 min. thereafter the levers controlling the boards carrying the tail-water samples shall be moved in such a manner that the bottles will cease to receive any water from the sampling pipes at that instant. The chemist in charge of the tail-water samples shall then proceed as quickly as possible to have his samples carefully carried to the chemical laboratory and properly cared for thereafter.

Salt-Solution Samples.—These samples shall be taken from the 3-in. pipe leading from the salt-solution tank to the suction of the 8-in. centrifugal pump at a point as near as practicable to the suction pipe. There shall be five of these 1-qt. samples, marked A, B, C, D, and E. It shall be the duty of the chemist in charge of these samples: first, to ascertain the time of duration of the test; second, to divide that time into five equal parts; and third, to see that the samples are taken in sequence, beginning with A and ending with E, each one being held under the sample cock for one-fifth of the duration of the test. It shall also be his duty to see that the sampling cock gives a uniform discharge during the taking of any one sample, and that this rate of discharge is such as nearly to fill the bottle during the particular time devoted to the particular sample in question. All the other requirements for cleanliness and nicety in the work connected with sampling shall be observed by all the chemists, in order to secure the desired degree of accuracy for the turbine tests. In particular, all sample bottles, after having been previously cleaned, shall be rinsed with a

portion of the sample water before being filled with another portion which is to constitute the sample proper.

Reagents.—There are three principal reagents connected with the turbine tests. The first is the commercial salt, which has been purchased in large quantity, for the purpose of making the salt solution. This salt contains more or less sand, also pieces of paper, chips of wood, and other extraneous substances, which are largely screened out during the process of charging the salt-solution tank. About 12 000 lb. are to be dissolved in the 5 000-gal. tank provided for the purpose. The resulting solution is then injected into the head-water through the twelve distributing pipes. The object of these distributing pipes is to assist in getting a good mixture of the salt solution with the feed-water for the turbine.

Silver Nitrate.—The second reagent used in this work is the centi-normal, or approximately centi-normal, solution of silver nitrate. Although it is not necessary that this solution should be standardized with the highest degree of accuracy, it is desirable that some degree of precision be required in determining the weight of silver nitrate dissolved per liter of distilled water. This is for the purpose of securing uniformity of strength from day to day. The general procedure for making the silver nitrate solution shall be as follows: About 14.5 grammes of silver nitrate shall be dissolved in 1 liter of distilled water. In weighing this quantity of silver nitrate for this purpose, the margin of error allowed in the weight may be taken at 0.05 gramme. After this solution is made to the extent of 1 liter in a dark-colored bottle, it shall be carefully preserved in a covered box where it will be entirely protected from the light except at short intervals when the solution is to be taken from the bottle. The solution required in the titration is to be made up from this solution at various times when needed, by diluting 100 c.c. to 1 liter with distilled water. In case larger quantities are needed, correspondingly larger quantities may be diluted.

It is an absolute rule, in reducing tests in the laboratory, that the same silver nitrate solution be used during any one particular test, as this rule is imperative in order to eliminate the errors of titration due to the excess of silver nitrate required to give a definite end reaction and otherwise to secure precision.

Chromate of Potassium.—Chromate of potassium shall be used as an indicator. This solution shall be made by dissolving 50 grammes in

1 liter of water, or, if larger or smaller quantities are desired, in corresponding proportions.

Quality of Reagents.—In the case of all the foregoing reagents, except the salt, chemically pure chemicals shall be used.

Titrations.—All the samples are generally taken and treated in such a way that the titration will require about 50 c.c. of silver nitrate. It will be necessary, therefore, to use 100-c.c. burettes, as, in many cases, the titration may exceed 50 c.c. Further than this, the laboratory procedure reduces each sample, either by dilution or evaporation, to about 10 c.c. in a casserole, so that the titrations of all samples are nearly identical in character, as the samples contain nearly the same quantity of chlorides at approximately the same concentration. Wherever possible, the method of balanced evaporations, Section 45, shall be used in concentrating by evaporation.

In order to secure uniformity of treatment, several rules must be strictly observed by the chemists when titrating samples.

Procedure.—

1.—The burette shall be filled to the zero of the scale, as nearly as practicable without loss of time, say to 0.4 or 0.3 c.c. Care must be taken to scrape off all surplus solution from the discharge orifice of the burette with a clean glass rod and to see that there is no surplus solution clinging to the top of the burette tube on the inside where it would be likely to fall into the solution below, thus causing an error in the estimate of the quantity of nitrate used in the ensuing titration.

2.—Take a reading of the burette.

3.—Record this reading on the form for the purpose, also noting the number of the burette beside this reading.

4.—Place the casserole containing the samples to be titrated under the burette.

5.—Introduce one drop of indicator into the sample by using a dropping bottle.

6.—One minute, approximately, after the first reading of the burette, take a second reading and record it immediately under the first. In general, these readings will be found to agree. If not, wait another minute, take a third reading, and record it immediately under the second. The third reading should agree with the second. If not, continue to take and record readings one minute apart until two consecutive readings, taken in this manner, agree.

7.—The stop-cock of the burette is now to be adjusted so that about two drops per second of silver nitrate will fall into the sample being titrated. The burette must be adjusted in the support so that the drops will not fall far enough to cause any splashing of the solutions, thus preventing losses over the side of the casserole.

8.—While the silver nitrate is thus being discharged into the sample, the observer has time to rinse a glass stirring rod with distilled water and to stir the sample with it in order to secure a thorough mixture, meantime watching the level of the silver nitrate solution in the burette and keeping the stop-cock adjusted so as to maintain the rate of discharge at about two drops per second.

9.—For each 10 c.c. of silver nitrate admitted to the sample in titration, one drop of chromate of potassium indicator is to be added to the sample as the level of the silver nitrate solution falls past the corresponding graduation mark on the burette. The object of this is to keep the quantity of indicator present in the sample proportional to the quantity of silver nitrate consumed, and also proportional to the volume of solution in the casserole. The color of the sample is also thus preserved as nearly uniform during the titration as possible.

10.—As soon as the titration nears the end point, the orange tint which appears on the admission of each drop of nitrate will tend to persist a longer time as the solution is stirred continuously with the glass rod. A little experience with samples of a particular class will enable the observer to tell when the titration is within about 2 c.c. of the end.

11.—When the titration is thus brought within 1 or 2 c.c. of the end, the observer must readjust the stop-cock of the burette so as to retard the rate of the discharge of silver nitrate to about one drop in 2 or 3 sec., stirring the solution thereafter continuously and scrutinizing the changing tints of the solution closely. Finally, a drop of silver nitrate will fall into the casserole which causes the solution to take a faint, though perfectly definite, orange tint. When this occurs the observer must be prepared to close the stop-cock instantly so as to stop the discharge from the burette. On continuing the stirring for 30 or 40 sec., the orange tint may gradually fade out, giving place to the former lemon-yellow tint. If this is the case, add one more drop of silver nitrate from the burette, and continue the stirring. By pursuing this course, a drop from the burette will be finally admitted into the casserole which will bring the solution to a very faint but definite

and permanent orange tint. This is the end point sought. Care must be taken before reaching this stage to see that there is no surplus drop of silver nitrate clinging to the bottom of the burette after reaching the end point, otherwise the burette reading will be erroneous, and an error will have been committed. The best safeguard at this stage is to remove each drop as it forms at the tip of the burette with the end of the glass stirring rod and introduce it in this way into the solution, closing the stop-cock each time before removing the drop.

12.—Read the burette scale and record the reading on the form for the purpose. A minute later check the reading and indicate the check by a check mark opposite the last reading.

If the solution has not been drawn from the burette faster than permitted by these rules, it will rarely be found that a third reading at the end of the titration is necessary.

13.—The observer is now to compute the number of cubic centimeters of silver nitrate consumed in the titration. After checking his calculation carefully, he is then to affix his initials opposite the result, and proceed to another titration, the sample for which shall be selected by the rules for group titrations, Section 48.

Preparation of Salt-Solution Samples.—

The operations in the laboratory should be arranged so that the various solutions will come into contact with nothing but glass or porcelain. For this reason the writer is not an advocate of the use of the "policeman" with a rubber or cork tip.

Special pipettes and glassware should be reserved exclusively for the strong salt solution. This will save much time in rinsing, and insure accuracy in the corresponding parts of the work.

1.—Shake the bottle containing the sample of salt solution to be treated.

2.—Take a clean 10-c.c. pipette, rinse it with a portion of this sample, allowing this portion to be discharged into a sink or waste receptacle.

3.—Fill the pipette again from the sample and withdraw very slowly from the solution so as to drain the outside of the pipette thoroughly.

4.—Let the sample in the pipette sink slowly to the graduation mark in the usual manner and, if necessary, scrape off the surplus drop at the tip with a clean dry glass rod.

5.—Also examine the tip and outside of the pipette to see if there is any surplus solution which can in any manner become incorporated

by accident with the solution to be delivered by the pipette. If so, it must be removed, being careful not to contaminate the contents of the pipette.

6.—Discharge the pipette into a liter flask, which has been previously cleaned and rinsed with distilled water. The neck of this flask must be free from drops of distilled water when the salt solution is introduced. The manner of discharging will depend on the manner of calibrating the pipette by the chemists.

7.—Fill the flask to the graduation mark with distilled water, stop the bottle, invert a few times, and add a few more drops, if necessary, to correct the shrinkage. Make a perfect mixture by stopping the bottle and inverting it from thirty to forty times, giving it a shake each time and allowing the air to pass from top to bottom and bottom to top after each inversion.

8.—Take the temperature of both the salt solution and the distilled water immediately after the sample, or samples, have been diluted as just described.

9.—Record these temperatures on the forms provided for the purpose, and observe whether the level of the solution in the flask when held vertical is still at the graduation mark.

10.—A 10-c.c. pipette full of the dilution just described delivers into a casserole a sample of dilute salt solution ready for titration. Chemists must observe the rules already given for the discharge of pipettes.

11.—Take and record the temperature of the dilution in the liter flask immediately after charging all the casseroles which are to contain samples for titration from this flask.

12.—Empty all flasks and other receptacles containing solutions for which there is no further use.

Normal Head-Water Samples.—These samples are of the normal canal water taken in the head-race before the water receives the salt solution from the distributing pipes. Four 1-gal. sample bottles are nearly filled with this water. Dilutions of salt solution with portions of these samples are prepared for each test. As a general rule, only one rate of dilution will be used in reducing any given test.

Special Dilutions.—Several different rates of dilution, however, may be used in preparing the normal head-water samples for titration.

Three examples follow. Observe carefully the general rule for making accurate dilutions, Section 89.

Dilution A.—Take five 10-c.c. pipettes of salt solution and dilute with 3 liters of normal head-water, thus making approximately 3 050 c.c. of stock solution in a gallon bottle. Shake thoroughly.

A_{123}.—One of these 3 liters for the dilution must come from each of the bottles containing normal head-water samples 1, 2, and 3. Label the stock solution thus prepared A_{123}.

A_{234}.—In precisely similar manner prepare another stock solution, taking 1 liter each from normal head-water samples 2, 3, and 4. Label this stock solution A_{234}.

Dilution B.—Take four 10-c.c. pipettes of salt solution and dilute with $2\frac{1}{2}$ liters of normal head-water, thus making approximately 2 540 c.c. of stock solution in a gallon bottle. Shake thoroughly.

B_{12}.—One of these $2\frac{1}{2}$ liters for the dilution must come from normal head-water sample bottle 1 and the remaining $1\frac{1}{2}$ liters from bottle 2. Label this stock solution B_{12}.

B_{34}.—In similar manner prepare another stock solution, taking 1 liter from normal head-water sample 4 and the remaining $1\frac{1}{2}$ liters from normal head-water sample 3. Label this stock solution B_{34}.

Dilution C.—Take three 10-c.c. pipettes of salt solution and dilute with 2 liters of normal head-water, thus making approximately 2 030 c.c. of stock solution in a gallon bottle. Shake thoroughly.

C_{12}.—One of these liters for the dilution must come from each of the bottles containing normal head-water samples 1 and 2. Label this stock solution C_{12}.

C_{34}.—In similar manner prepare another stock solution, taking 1 liter from each of the bottles containing normal head-water samples 3 and 4. Label this stock solution C_{34}.

89.—To Make Accurate Dilutions with the Chemical Equipment in the Laboratory.—Let it be required to dilute n pipettes of salt solution with m liter flasks of solution which will be called water, the whole to be mixed in a larger receptacle. Use only flasks which contain a given quantity of water, nominally 1 liter. Divide as nearly as possible the n pipettes of salt solution among the m flasks, discharging them into the flasks according to the rules for pipettes, and preparing the flasks according to the rules for flasks.

Fill the flasks to their graduation marks with water and shake thoroughly, according to the directions already given. Let the flasks rest on a table for a few minutes and then, if necessary, add a drop or two more of water to restore the level of the meniscus to the graduation mark.

Empty all the flasks into the receptacle which has already been cleaned, rinsed with distilled water, and drained, as previously directed for flasks. Shake thoroughly, empty the contents, and repeat the entire procedure, except that the final mixture in the receptacle is to be retained as the desired mixture.

The total contents of the flasks divided by the total discharge of the pipettes is the ratio of dilution.

In case it is desired to make a dilution up to a given ratio of mixture, the rule is correspondingly the same as the foregoing except that the n pipettes are discharged into the receptacle instead of the flasks, after which the m flasks of water are poured in. The flasks are finally rinsed into the receptacle with the final mixture therefrom. The resulting ratio of mixture is the total contents of the m flasks divided by the total discharge of the pipette, or pipettes, as the case may be. When n is not a multiple of m it will be on the side of precision to dilute for ratio of mixture.

Further Treatment of Special Dilutions.—In every test, therefore, there will be two stock bottles containing the special dilutions or stock solutions. These special dilutions are to be further diluted by discharging a 10-c.c. pipette of the special dilution into a liter flask which has been previously cleaned and rinsed with normal head-water. The flask is then filled with normal head-water in the usual manner and the stopper tightly adjusted in the neck. The flask must then be alternately inverted and righted forty times, allowing the air bubble to rise to the highest point within the flask on each half turn. When satisfied that the mixture is uniform, the sample is to be divided into two half-liter samples by pouring it into two half-liter flasks which have been previously rinsed with distilled water, the liter flask containing the original sample being finally rinsed with distilled water, which may be divided between the two half-liter flasks. Each of these half-liter samples is then to be poured into the particular separatory funnel which has been reserved for it. The flask is then to be rinsed

with a small portion of distilled water which is finally poured into the separatory funnel.*

Prepare ten such half-liter samples altogether, taking four from one of the stock bottles of special dilution and the remaining six from the other stock bottle. Mark each casserole, with a label attached to the handle, with the symbol which indicates the particular stock bottle out of which the sample to be evaported in the casserole was taken.

These samples are next to be evaporated over the water-bath, the attendant maintaining a volume of about 40 c.c. in each casserole during the evaporation. This is effected by drawing from the separatory funnel over each casserole at proper intervals of time sufficient solution to restore the level of the liquid in the casserole to the proper elevation.

When all the sample which will discharge from any one funnel into its casserole has been drawn off in this manner, the attendant must rinse down the sides of the funnel with a small quantity of distilled water which is also admitted to the casserole at the proper time.

Great care must be taken in all the operations connected with these evaporations to see that no part of any sample is lost, and that all the salt of any sample is finally collected in the proper casserole, also to see that the level of the solution in every casserole is maintained as nearly fixed as reasonable care can insure.

When all the salt from any sample is collected in this manner, there should be about 40 c.c. of solution in the casserole. The evaporation is then to be continued until the volume of the liquid in the casserole is reduced to about 10 c.c.

This can be accurately estimated by the attendant by comparison with the volume of water, in another casserole of the same size and shape, which results from the delivery of a 10-c.c. pipette.

The casserole containing this final concentration of salt is then to be placed on the square reserved for this purpose on the sample table.

This sample is then ready for titration.

Tail-Water Samples.—There are eighteen of these samples, taken in gallon bottles from eighteen different locations in the tail-race. The numbers are not consecutive, being, in particular, 21 to 32, both

* This procedure was adopted so as to make effective use of the particular glassware in the laboratory.

inclusive, 41, 42, 43, 51, 55, and 56. This irregularity in numbering resulted from a series of changes which were made in the locations of the tail-race sampling pipes.

Evaporation of Tail-Water Samples.—One-half liter is measured from each of the eighteen samples into the corresponding separatory funnel, the half-liter flask in each case being rinsed with a small portion of the sample before being filled with it and with a small portion of distilled water after being emptied, this portion of distilled water finally being poured into the separatory funnel to prevent any loss of salt.

The evaporation is then to be conducted in precisely the same manner as that given for the evaporation of the special dilutions.

Modified Procedure for Tail-Water Samples.—It is desirable in some cases to reduce the number of evaporations of tail-water samples. In order to make the process clear, it will aid to observe that the number and relative location of each sample in the tail-race is indicated by the following diagrammatic tabulation:

UPPER DRAFT-TUBE (LOOKING UP STREAM).

WEST.		EAST.	
43	29	55	
23		32	56
51	31	41	

LOWER DRAFT-TUBE (LOOKING UP STREAM).

WEST.		EAST.	
25		28	22
21	27	26	
42		30	24

The samples, therefore, may be classed according to the particular half of the draft-tube to which they belong, thus:

UPPER DRAFT-TUBE.	WEST HALF	43	29
		23	
		51	31
	EAST HALF	55	
		32	56
		41	

Lower Draft-Tube.	West Half	25	
		21	27
		42	
	East Half	28	22
		26	
		30	24

The samples represent approximately equal areas of cross-section of the draft-tube. The samples of any half of a draft-tube, therefore, will be combined by mixing equal parts, say ½ liter of each, in a gallon bottle which has been previously cleaned and then rinsed with a mixture of approximately equal portions of the corresponding samples.

Thus, for the west half of the upper draft-tube, mix ½ liter of each of Nos. 43, 51, 23, 29, and 31. For the west half of the lower draft-tube, mix ½ liter of each of Nos. 21, 25, 42, and 27.

Shake the resulting stock solutions, consisting of 2 or 2½ liters in gallon bottles, thoroughly, and label the bottles according to the following scheme.

Upper Draft-Tube, West Half..... U. W.
Upper Draft-Tube, East Half..... U. E.
Lower Draft-Tube, West Half..... L. W.
Lower Draft-Tube, East Half..... L. E.

Measure accurately from each stock solution two ½-liter samples which are to be placed in the separatory funnels reserved for the particular samples in question.

In all cases the volumetric flasks must be cleaned and rinsed with a portion of the stock solution from which the sample is to be taken before being filled with the sample. Moreover, the flask from which any sample has been discharged into its separatory funnel must be finally rinsed with a small portion of distilled water, which portion must then be discharged into the separatory funnel, so as to insure the capture of all the salt of the sample.

Each casserole must finally be labeled with the symbol which pertains to the particular stock solution which is to be evaporated in it.

In all cases the same separatory funnel and location on the water-bath should be reserved for the same sample in different tests.

PART III.

THE TESTING PLANT.

SUMMARY.

90.—In Part III the general plan for the salt-solution tank and distributing system is described.

The current-meter rack and platform, which also carries the salt-solution distributing pipes, is described and illustrated. This structure with its equipment can be moved bodily by the crane from one unit to another.

The salt-dissolving box and platform is illustrated. By this invention 7 tons of commercial salt can be put into solution in a 5 000-gal. tank within 1 or 2 hours, according to circumstances. Its operation is continuous. The solution is very nearly saturated.

The sprinkler system is described and illustrated.

The large iron calibrator, or pipette, is described.

The tail-race sampling pumps are illustrated and the method of operating them explained.

The chemical laboratory and equipment and the direct-current metering instruments are illustrated.

As the method of measuring the discharge of hydraulic turbines by a chemical introduced into the feed-water is a relatively new branch of engineering, especially when applied to hydro-electric units of large capacity, a somewhat detailed description of the chemical testing plant, as it was installed for the tests considered herein, will be necessary, in order to make clear the exact nature of the operation of testing as it was conducted by the writer. As a matter of fact, the methods were entirely novel in nearly all respects.

The magnitude of the chemical operations conducted may be understood better when it is explained that each test required from 4 to 6 tons of commercial salt, which was used as a chemical reagent. The problem of getting this quantity of salt into a solution very near to the saturation point alone offered considerable apparent difficulty at the outset. Numerous preliminary tests were made to ascertain the probable length of time which would be required to make such a solution in a 5 000-gal. tank, with the apparent result that it would require several hours and great care. It was apparently very difficult to make

a saturated solution of 1 liter capacity in a short period of time. On careful reflection, however, it was decided to make what the writer terms a dissolving box, and this invention proved to be very efficient in producing salt solutions nearly up to saturation. Moreover, it was found by actual test that 7 tons of salt could be dissolved and the resulting solution pumped into a 5 000-gal. tank in less than 1 hour.

In the case of tests which had been conducted in Europe, on turbines discharging a very small quantity of water, it appears to have been the custom to filter the salt solution before admitting it to the solution tank. This appeared to the writer to present too many chances for delay, and, therefore, it was decided to try out a method which would not demand the additional time necessary for filtration.

91.—General Plan for Salt-Solution Tanks and Distributing System.—Fig. 9 is the writer's original diagrammatic sketch for the salt-solution tanks and distributing system. Very little change was made in this general plan when laying out the details of the actual system as it was installed. On the left is the dissolving box, which is substantially of the same dimensions as the one actually used. Instead of a 3-in. pipe, however, leading to the salt-solution screens, as shown in the sketch, a trough about 8 by 10 in. in cross-section led from the top of the dissolving box on a steep slope to a point where its discharge was emptied into a hood fitting over the end of the trough, hanging vertically therefrom and provided with screens of very fine mesh in the bottom. This hood could be taken from the trough at any time for the purpose of emptying the accumulations of rubbish. The latter consisted principally of chips of wood and other extraneous matter which was included as impurities of the low commercial grade of salt used for the tests. At several points in the trough there were screens of somewhat coarser mesh than those at the bottom of the hood. These were slipped into slots in the sides of the trough and served to remove the coarser impurities without allowing them to fall into the hood. The salt solution, after passing through the screen at the bottom of the hood, fell into a 5 000-gal. tank. It was originally intended to have a 6 000-gal. tank, but the one supplied contained only 5 000 gal. and appeared to fulfill all necessary requirements. The hood into which the salt solution fell from the trough was approximately 12 in. wide, 15 in. long, and 18 in. high; the screen, therefore,

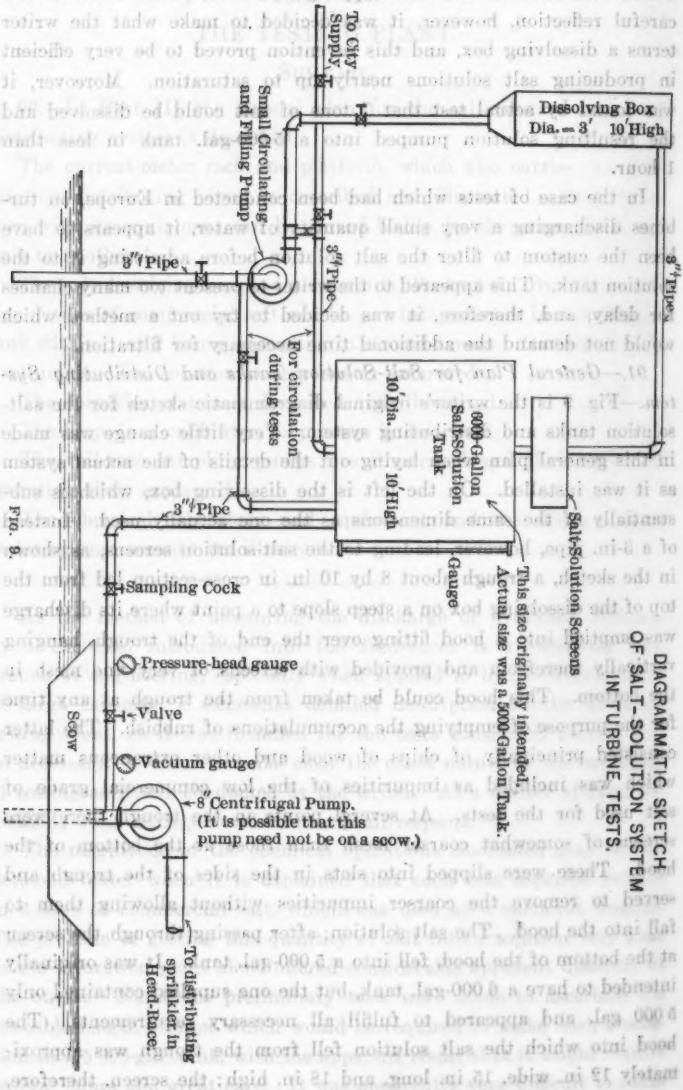

FIG. 9. DIAGRAMMATIC SKETCH OF SALT-SOLUTION SYSTEM IN TURBINE TESTS.

offered an effective area of about 12 by 15 in. This screen had forty meshes to the inch.

At the side of the salt-solution tank there was a 10-ft. gauge-board, having a vertical slot along the axis of the board sufficiently deep and wide to admit a glass tube of 1 in. inside diameter, the bottom of which was connected to the bottom of the tank by a short length of 1-in. rubber tubing. There were also two valves, one being at the bottom of the glass tube for the purpose of emptying the gauge glass in order to admit fresh solution from the tank. The object of this operation was to have the gauge glass full of solution of the same density and at the same temperature as that contained by the large tank. The other valve was at the end of the 1-in. rubber tubing, and served to cut off the flow from the tank when it was desired to empty the gauge glass. It is important to have the valve which empties the gauge glass immediately at the bottom of that glass, rather than next to the valve beside the tank. The object of this is to empty the gauge glass without completely emptying the hose, otherwise, when it is attempted to fill the gauge glass again, air is likely to be entrained in the solution and thus cause some difficulty in securing a perfect meniscus in the gauge glass.

A small 3-in. centrifugal pump, driven by a small motor, was used to circulate the water. It was connected, in about the manner shown diagrammatically in the sketch, to the dissolving box and salt-solution tank. Instead, however, of its suction dipping down into the head-race, as shown in the sketch, it was connected directly to the city water supply system. In using the city water supply, the pump tender must take great care that the full city pressure is not allowed to act on the pump casing, as it is likely to burst.

It will be seen from the arrangement of the 3-in. piping and valves that the circulating pump serves a double purpose. It is capable of circulating the water up through the dissolving box, over through the 8 by 10-in. trough and into and through the 5 000-gal. tank; or, it may simply circulate the solution in the tank by drawing it off through the suction and discharging it back into the bottom, the salt-dissolving box under these circumstances being cut off by a valve in the 3-in. pipe. The object of this latter operation is to secure a perfect mixture in the salt-solution tank at a uniform temperature; also to dissolve

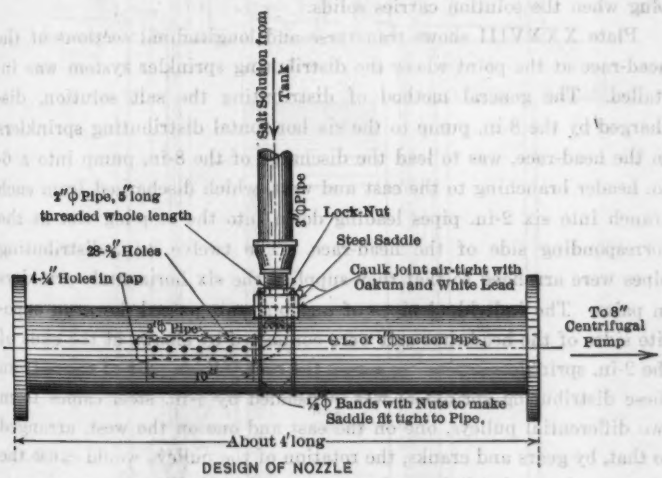
any salt which may find its way into the 5 000-gal. tank and settle to the bottom.

The operation of charging the tank with salt solution consists in, first, emptying and cleaning the large tank. This may be done through an opening in the bottom which is provided with a large nipple and gate-valve. The small circulating pump is then started, the valve leading to the dissolving box being open and the water being taken from the city supply, the valves in the 3-in. pipes leading to the large tank, of course, being closed. As soon as the water begins to flow into the dissolving box, salt is shoveled in at the top. The salt settles down through the water which is rising in the dissolving box and flowing over into the large tank through the 8 by 10-in. trough. The rate of water supply and the rate at which salt is shoveled into the top of the dissolving box must be properly adjusted by trial in order to secure the maximum efficiency. It was found that the capacity of the circulating pump was just about sufficient, when somewhat throttled down, to dissolve salt at the rate at which two men could shovel it in at the top. One or two attendants are required to keep the screens free from débris as the water flows into the solution tank. It was not found necessary to remove the hood during the operation of charging the tank, and this, indeed, would not be desirable at any time during the operation, as it would be likely to allow the admission of débris into the solution tank with the consequent danger of plugging the distribution system, especially at the point where the water is admitted into the suction of the 8-in. centrifugal pump which supplies the distributing sprinklers.

There was always a considerable percentage of fine sand carried by the salt, and this passed through all the screens and fell into the large tank, after which it settled on the bottom to a depth of $\frac{1}{8}$ to $\frac{1}{4}$ in. for each charge. The tank was not always cleaned after each filling, as this layer of sand caused no inconvenience. The sand was very fine and compact, and was not likely to be dislodged by currents of salt solution in the tank. The time required to charge the tank varied from somewhat less than 1 hour to 2 hours or more, according to circumstances.

A 3-in. pipe led from the bottom of the salt-solution tank to the suction of the 8-in. centrifugal pump, shown on a scow in Fig. 9. This scow was not used at any time in the tests. Originally, the object in

having the scow was to maintain a constant suction head on the large centrifugal pump, but it was not found necessary to have a uniform supply of water from this pump and consequently no scow was necessary. Had the scow been used, it would have been necessary to have flexible joints in the pipe lines leading to the centrifugal pump. As a matter of fact, the pump was on the deck of the power-house platform immediately over one of the piers of the head-race. In this position the suction lift varied from 17 to 23 ft., but the pump seemed to work very satisfactorily under any of these conditions of lift. There



DESIGN OF NOZZLE
FOR INJECTING SALT SOLUTION
INTO SUCTION OF 8-INCH CENTRIFUGAL PUMP.

FIG. 10.

was no screen over the intake of the 3-in. pipe leading to the 8-in. pump. The writer is inclined to believe that it would have been wiser to have a screen over the intake of the 3-in. pipe, although there was no difficulty in this respect during any of the tests.

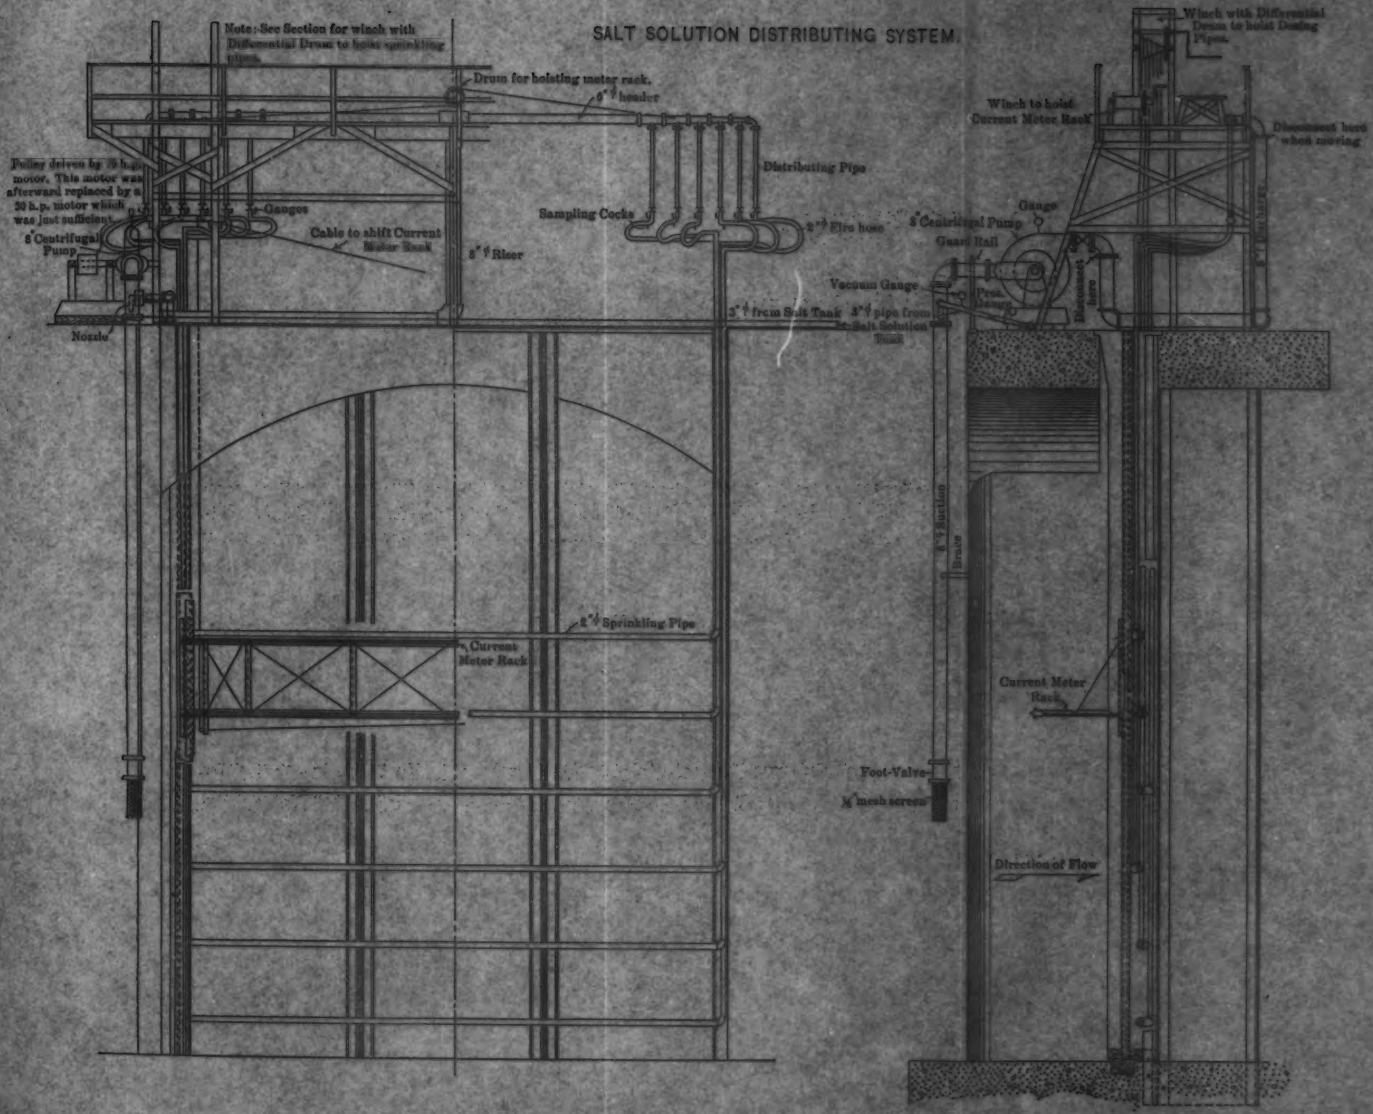
Fig. 10 shows diagrammatically the method of introducing the salt solution into the suction of the 8-in. centrifugal pump. The sprinkler attached to the elbow within the 8-in. suction points against the flow of the water on its way from the canal water level to the pump. This sprinkler was 10 in. long and had twenty-eight ⅜-in. holes through its convex surfaces, and four ¼-in. holes in the cap.

It may not have been necessary to provide the end of the 3-in. salt-solution pipe with such a sprinkler, but the writer is of the opinion that this aids materially in securing a perfect mixture of salt solution with the feed-water for the centrifugal pump. There was little time for experimentation in this respect, so that there was no evidence whatever bearing on the design of such a sprinkler. It would appear to the writer that the holes for this sprinkler should have been smaller, so as to project jets of solution as far as possible into the body of the suction water feeding the pump. If the holes are too small they will plug when the solution carries solids.

Plate XXXVIII shows transverse and longitudinal sections of the head-race at the point where the distributing sprinkler system was installed. The general method of distributing the salt solution, discharged by the 8-in. pump to the six horizontal distributing sprinklers in the head-race, was to lead the discharge of the 8-in. pump into a 6-in. header branching to the east and west, which discharged from each branch into six 2-in. pipes leading down into the stop-log slot at the corresponding side of the head-race. The twelve 2-in. distributing pipes were arranged so that they supplied the six horizontal sprinklers in pairs. The individual pipes of any one pair passed down on opposite sides of the head-race and were connected by elbows at the ends of the 2-in. sprinklers extending across the race. Each pair of risers from these distributing sprinklers was suspended by ¼-in. steel cables from two differential pulleys, one on the east and one on the west, arranged so that, by gears and cranks, the rotation of the pulleys would cause the pipes to rise and fall in such a manner that they were always equidistant, thereby dividing the cross-section of the head-race into six equal horizontal strips. The object of this was to keep the salt solution as uniformly distributed over the cross-section of the head-race as possible, and to permit of adjusting the levels of the pipes to the level of the surface of the water in the canal, which was likely to vary 6 or 8 ft. from time to time.

The necessity for this adjustment demanded flexible connections between the distributing pipes leading from the 6-in. header and the risers leading up from the sprinklers. This was accomplished by using sections of 2-in. hose of sufficient length to admit of the necessary motions. See Figs. 22 and 23.

SALT SOLUTION DISTRIBUTING SYSTEM.



The 6-in. header which has just been briefly described was carried across the top of a wooden platform resting on a frame, which is shown by Fig. 11. This will be better understood by examining Figs. 22 and 23, which are explained in detail in Section 97.

92.—Current-Meter Rack and Platform.—The platform, Fig. 11, which has just been mentioned, was constructed primarily for the purpose of suspending the current meters, which were carried on a steel frame or rack. This meter rack, Fig. 12, was constructed in two sections or leaves which were capable of folding so as to admit of the whole being dropped through the head-gate opening and into the stop-log slots, where it rested against two steel guides composed of two channels. These channels were provided at the bottom with a pair of legs, or spreaders, so that the channels could be dropped down the stop-log slots in a vertical position in such a manner that when the spreader came in contact with the bottom the legs would spread apart and hold the channel rigidly in its proper position at the bottom. The channels were then made fast at the top, so as to be practically in a vertical position, thereby acting as guides for the current-meter rack at each side of the head-race. The object of this arrangement was to admit of placing and removing the guides without the necessity of shutting down the unit or emptying the head-race. These channels seemed to work very satisfactorily, and could be placed and removed in a few minutes. The current-meter rack was suspended at each end by a ¼-in. steel cable which led vertically up to a pulley at the corresponding end of the current-meter platform; these two cables then passed around the drum of a small winch, by which the rack could be raised or lowered at pleasure.

In order to lower the rack into the head-race, its two leaves were closed and the whole was dropped through the head-gate opening into the stop-log slot until it was low enough to admit of opening the horizontal leaf into position. The current meters had been previously attached to the rack, so that they were then ready for operation. The rack with the current meters could thus be lowered to the bottom of the head-race or to any intermediate position desired. The horizontal leaf of the rack operated on vertical pivots, so that it could be shifted toward one side or the other of the race, as indicated by the dotted lines in Fig. 12, only one-half of the meter rack being shown. The rack was equipped with five pieces of angle iron, about 1 ft. 7½ in.

METER RACK

long, and these were always parallel to the axis of the head-race, which was approximately parallel to the direction of the current. To these five pieces of angle iron the five current meters were rigidly attached, with their axes pointing directly up stream. There were two steel cables, arranged as shown in Fig. 12, leading around pulleys at each end of the rack, for the purpose of enabling the current-meter tenders to shift the position of the meters from one side to the other. This permitted of two points of operation for each meter, thereby giving ten meter points for any elevation of the rack. Five of these meter points were determined by the position of the horizontal leaf when it was shifted to the west and five when it was shifted to the east, in any one elevation. The westerly position was limited by the contact with the west wall of the west end of the long angle iron extending across the raceway. The easterly position was limited by the contact of the other end of the angle iron with the east wall.

The general method of operating this rack was to divide the depth of water into ten equal parts and then operate the rack successively at the middle of each of these parts, thus giving ten elevations for the meter rack and therefore one hundred meter readings for one sweep of the head-race by the meter rack. As in the case of the six horizontal distributing pipes, the ten meter elevations were always adjusted to the elevation of the water surface, so that the horizontal leaf of the meter rack represented the median line of one of the ten equal horizontal strips into which the race was divided.

Of the five current meters used, two were Haskell meters of the screw type; two were Ott meters of the screw type; and one was a small Price meter, very kindly lent by H. W. King, M. Am. Soc. C. E., of the University of Michigan. The two Ott meters were lent through the courtesy of the Allis-Chalmers Company.

When it was desired to move the testing equipment from one unit to another, the meter rack was raised to its highest position under the platform; the connection of the discharge to the 6-in. header and the flexible hose connections to the risers from the sprinklers were removed; the connections of the cables to the risers from the sprinklers were also removed, the risers and sprinklers being temporarily lashed to a long I-beam. Then the entire platform with its equipment was shifted to one side, using the traveling crane, while the I-beam carrying the sprinklers and current-meter guides was being

moved by the crane for the purpose of lowering its load into the stop-log slots of the unit to be tested.

The suspension platform was then taken up by the crane and placed over the head-race into which the sprinklers and guides had been lowered, after which all its connections were put in place and the testing equipment was adjusted for use in its new location.

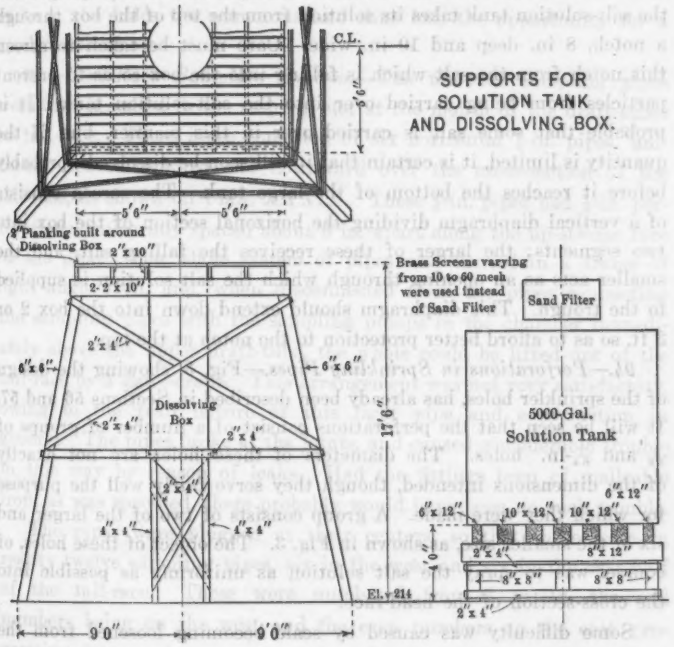

FIG. 13.

93.—Salt-Dissolving Box and Platform.—Fig. 13 shows the salt-dissolving box and platform. This box consisted of a white pine tank, 3 ft. in diameter and 10 ft. high. The staves were of 2-in. plank dressed to about $1\frac{7}{8}$ in. in thickness. The floor of the platform was constructed so that the top of the tank projected about 10 or 12 in. above it. At the edges of the floor there was a 2-in. plank bulwark, about 18 in. high, so that salt could be thrown on the platform without rolling off. In constructing another such platform, the writer would place the dissolving box eccentrically, relative to the platform,

as it is not necessary for the men to stand on opposite sides of the box. With such a scheme, the size of the platform might be made somewhat smaller, and at the same time more convenient. In making use of this box, an ordinary sand screen, of about ¼-in. mesh, is placed over its top opening in such a manner that when salt is thrown on the screen it will fall through and into the box. The trough leading to the salt-solution tank takes its solution from the top of the box through a notch, 8 in. deep and 10 in. wide. Care must be taken to screen this notch from the salt which is falling into the box so as to prevent particles from being carried over into the salt-solution tank. It is probable that some salt is carried over in this manner, but, if the quantity is limited, it is certain that it will soon be dissolved—probably before it reaches the bottom of the large tank. The screen consists of a vertical diaphragm dividing the horizonal section of the box into two segments; the larger of these receives the falling salt, and the smaller acts as an opening through which the salt solution is supplied to the trough. This diaphragm should extend down into the box 2 or 3 ft. so as to afford better protection to the notch at the top.

94.—Perforations in Sprinkling Pipes.—Fig. 3, showing the design of the sprinkler holes, has already been described in Sections 56 and 57. It will be seen that the perforations consist of a number of groups of $\frac{5}{32}$ and $\frac{7}{64}$-in. holes. The diameters of these holes are not exactly of the dimensions intended, though they serve fairly well the purpose for which they were made. A group consists of two of the larger and six of the smaller size, as shown in Fig. 3. The object of these holes, of course, was to spray the salt solution as uniformly as possible into the cross-section of the head-race.

Some difficulty was caused by scale becoming loosened from the interior surface of the pipe system and plugging the holes. It would seem desirable, therefore, to have the holes sufficiently large to eliminate this trouble. Holes ¼ in. in diameter would serve this purpose well, but in any case it would be advisable to have a T on each sprinkler pipe with a perfectly tight valve on the extremity, provision being made for the operation of the valve from above at such times as it might be desired to flush out the pipe system. This was not done in the tests described, but it is suggested as a safeguard in other tests. No serious difficulty, however, was caused by the plugging of the holes after the pipes had been thoroughly flushed once or twice

and blown out by compressed air. It must be carefully borne in mind, in designing sprinklers, that the centrifugal pump should be properly proportioned to project the jets far away from the orifices, for the purpose of reaching all parts of the cross-section with salt solution. It would be preferable, therefore, to have fewer holes, thus creating a larger head for the injection of salt solution, rather than to have the holes too numerous and thus lose the opportunity for a good distribution.

95.—Tail-Race Sampling System.—The tail-race sampling pipes were first installed in the stop-log slot at the mouth of the draft-tubes or tail-race. These pipes consisted of six horizontal ¼-in. pipes, uniformly spaced upward and downward over the cross-section of the tail-race, as shown on Plate XXXIX. These ¼-in. pipes had ⅛-in. perforations, uniformly spaced about 6 in. apart along the up-stream face of the pipe. The whole system of pipes was carried in a frame of light angle iron, and, when disconnected from the pipes connecting the sampling pipes with the sampling pumps in the chamber immediately above the upper draft-tube, the whole could be lifted out of the tail-race by a hand-crane. This arrangement was not very satisfactory, owing to the frail nature of this light pipe and construction in general. The pipes broke at the joints, and caused considerable trouble in this way by reason of leaks. Had the fittings been of malleable iron, as was specified, there probably would have been no such trouble.

The pipes were plugged at their centers, so that there were in reality twelve sampling pipes, six in the west and six in the east half of the tail-race. These were numbered from 1 to 12, the odd numbers being on the west and the even numbers on the east, progressing downward.

It gradually became evident that the sampling-pipe system could be improved by moving the whole back to the plane of the 4-in. pipes, which had been provided during the construction of the power-house for the admission of Pitot tubes into the tail-race at the mouths of the draft-tubes. This plane is about 8 ft. farther up stream, and has the advantage that the suction pipes leading to the sampling pumps do not pass through a layer of water which was not discharged from the turbines being tested, as was the case at the lower section, where the risers from the sampling pipes passed up through 6 or 8 ft. of

water which was swept back against the power-house wall and probably contained little or no salt other than that naturally in the river.

The caisson compartment shown in the lower part of Plate XXXIX was merely a suggestion as to how the samples might be taken by gravity without the necessity for sampling pumps. This caisson was neither constructed nor used in the tests.

The battery of eighteen sampling pumps stood in the chamber above the upper draft-tube, and was driven by a 10-h.p. motor. It will be described more completely in Section 97.

FIG. 14.

Fig. 14 shows the relative locations, in the upper sampling section, of the intakes of the eighteen sampling pipes which extended down through the 4-in. Pitot tube admission inlets. The numbers of the samples were the same as those shown in Fig. 14. It appears that there was no particular system in connecting up the sampling pipes with the sampling pumps, so that the numbers are not arranged as systematically as they are in the case of the sampling system at the lower section. However, the sample bottles were carefully numbered so as to correspond to the particular locations to which the same numbers are attached in the illustration, so that no ambiguity could result as

to the location in the tail-race from which a particular sample was taken.

96.—Relation of Testing Plant to Turbines.—Plate XL shows sections of the water passages for the turbine unit being tested, and also the head-race and penstock in which the turbines were placed. The upper and lower sections for the tail-race sampling system are also indicated in the longitudinal section. The relative location of the dissolving box and solution tank is also shown.

97.—Photographs of the Testing Equipment.—Fig. 15 is a general view showing the arrangement of salt-solution tanks, salt-distributing system, and current-meter suspension frame.

The salt was brought to the plant by rail, in carloads of 20 to 30 tons, and stored in bins at the west end of the gate-house beyond the extreme right of Fig. 15. The total capacity of the bins was about 100 tons, but probably they did not contain more than 80 or 90 tons at any one time. The hatchways of the bins were immediately under the traveling crane, so that the salt was readily handled by this crane in connection with a second crane at the junction of the gate-houses of the old and new power-houses.

The salt was carried by the crane in a large skip, having a capacity of slightly more than 1 ton. This was lifted to the platform of the dissolving box, where it was dumped. Two men then shoveled the salt rapidly into the box while the circulating pump took water from the city main, pumped it up through the dissolving box and over into the salt-solution tank through the 8 by 10-in. trough previously described.

A 3-in. supply pipe led the salt solution from the tank to the suction of the 8-in. centrifugal pump, at the left center of Fig. 15, immediately under the shed.

A section of the 3-in. pipe can be seen at the point where it enters the 8-in. suction of the centrifugal pump. The back of the vacuum gauge on the 3-in. pipe is also visible. The centrifugal pump can be seen, and also the wooden belt-guard leading from the pump to the motor.

The elevation of the water surface in the canal was evidently about 195.7 ft., so that the suction lift of the centrifugal pump was about 21.3 ft., the center of the pump being approximately at Elevation 217.

In Fig. 18 the salt-solution gauge reader can be seen on the gauge reading scaffold at the side of the gauge-board attached to the salt-solution tank. Two of the head-water sampling pumps, with their suction pipes leading down into the canal, are visible at the center of Fig. 15. Several of the 1-gal. sampling bottles are also visible beside the sampling pumps. One of the gauge-boards can be seen attached to the concrete wall of the entrance to the head-race of the turbine being tested. The head-water was not read at this cross-section, but at a point 5 ft. down stream from the trash racks, which are not visible in Fig. 15. The gauge-board indicates an elevation of water surface of about 195.7. There was another gauge on the opposite wall, and the two were used for the purpose of giving the elevation of the canal water at the current-meter section on each side.

The current-meter suspension frame and platform is at the left center, back of the centrifugal pump and shed. The 8-in. riser supplying the header on top of the platform, and also the top of the header itself, can be seen at the back part of the framework. The two winches carrying the differential pulleys at the ends of the platform, as well as the winch for the current-meter rack in the center of the platform, can be seen.

Fig. 16 shows the salt-dissolving box and salt-solution tank. The iron pipette for calibrating the tank stands between the tank and the right-hand leg of the frame supporting the salt platform. It consisted of a length of 12-in. pipe held in a four-legged wooden frame. The 2-in. pipe carrying the water glass was not attached to the top of the iron pipette at the time of taking the photograph. The 10-ft. gauge-board carrying the 1-in. glass tube in a slot along its center, together with the rubber tube attaching the bottom of the glass gauge to the bottom of the tank, is at the right of the salt-solution tank. The gauge reader's scaffold stands at the right of the gauge-board. The 3-in. riser leading from the circulating pump to the bottom of the salt-dissolving box is shown, also the pipe leading under the planks from the city water supply at the left. This pipe joins the pipe leading to the bottom of the salt-dissolving box, and may be disconnected from it by a gate-valve. A portion of the crane which assists in handling salt is at the extreme right.

Fig. 17 illustrates the operation of charging the salt-solution tank. A skip-load of salt has just been raised into position by the crane and

is about ready to be dumped on the salt platform. The sand screen immediately above the upper opening of the salt-dissolving box is in view.

One of the engineers may be seen knocking the débris from one of the screens which he has withdrawn from the slots in the 8 by 10-in. trough leading from the salt-dissolving box to the hood immediately over the salt-solution tank. This hood can be seen at the end of the trough. The tank was provided with a cover to protect the surface of the water from any falling débris and also to keep off the wind. Very little trouble was caused by waves forming in the tank, but the writer would suggest having a grilled float on the surface of the water in such a tank, in order to still the surface as completely as possible. This was not done during the tests described herein, and the result was that on several occasions the meniscus of the salt-solution gauge was not as steady as it might have been, thus introducing small errors into the calculation of the quantity of salt solution consumed during the particular tests in question.

At the extreme lower left is seen the box in which was placed the motor driving the small circulating pump, which latter is in view but somewhat obscured by the multiplicity of pipes, timbers, cables, and chain in its vicinity. The discharge pipe can be plainly seen leading vertically upward from the discharge of the pump.

The 3-in. supply pipe leading from the bottom of the salt-solution tank to the suction of the 8-in. centrifugal pump can be seen leading across the floor of the gate-house and making a right angled turn near the lower right corner.

Fig. 17 also gives a perspective down through the west gate-house toward the salt-storage bins and the chemical laboratory, which is obscured by the small concrete house enclosing the motors for the ice sluice-gates, the gears for which are shown near the lower right corner.

Fig. 18 gives another view of the salt-solution tank and salt-dissolving box connected by the 8 by 10-in. trough and hood.

The gauge reader may be seen at the left of the tank, making a record of the gauge reading.

The centrifugal circulating pump is much more plainly visible in this than in Fig. 17.

Fig. 19 gives a bird's-eye view of the salt-dissolving box, salt-solution tank and deck of the current meter and sprinkling pipe suspen-

sion platform. The differential pulleys and twelve suspension cables which were attached to the risers from the six sprinkling pipes are at the ends of the platform, and the winch for raising and lowering the meter rack is at the middle of the up-stream side of the platform. The 6-in. header fed by the 8-in. riser from the centrifugal pump may be seen on the deck of the frame. The 8-in. centrifugal pump is under the shed at the extreme lower right of Fig. 19. The left center foreground shows the tops of the racks in one of the units tested.

The screen for salt and a quantity of salt piled on the salt platform are in view.

Fig. 20 shows the centrifugal pump driven by a 75-h.p. motor, and the 8-in. discharge leading to the 8-in. riser and header on the platform. Parts of the twelve 2-in. distributing pipes leading from the header, six at each end, may be seen. The lever for operating the four head-water sampling pumps, the cross-head connecting the four plungers, the four plungers themselves, and the bottom parts of the suctions of these small pumps can be seen just above a collapsed section of 2-in. hose pipe leading from one of the distributing pipes to the sprinkler system. These sampling pumps were small hand-pumps supplied by the Deming Company, and the handles can be seen just above the cross-head and under the hand-lever.

Fig. 21 shows the iron pipette calibrator used in the calibration of the large salt-solution tank. The top and bottom of this calibrator are not plainly visible, but they were each conical in shape. The cone at the top was for the purpose of allowing the escape of air through the 2-in. pipe at the top when the calibrator was filled with water; the conical bottom was to facilitate draining the calibrator when it was emptied through the throttle valve at the vertex of the cone. The water-glass at the side of the 2-in. pipe projecting above the vertex of the upper cone was for the purpose of ascertaining the level of the water in the calibrator. A paper label can be seen pasted on this gauge. The label carried a mark at the proper elevation for a given capacity. The volume of water discharged from the calibrator was about 240 liters (8.466 cu. ft.) when it had been previously filled up to the mark with canal water.

The method of calibrating the tank was to set this calibrator down on the top of the rack platform, shown in Fig. 19, so that the water in

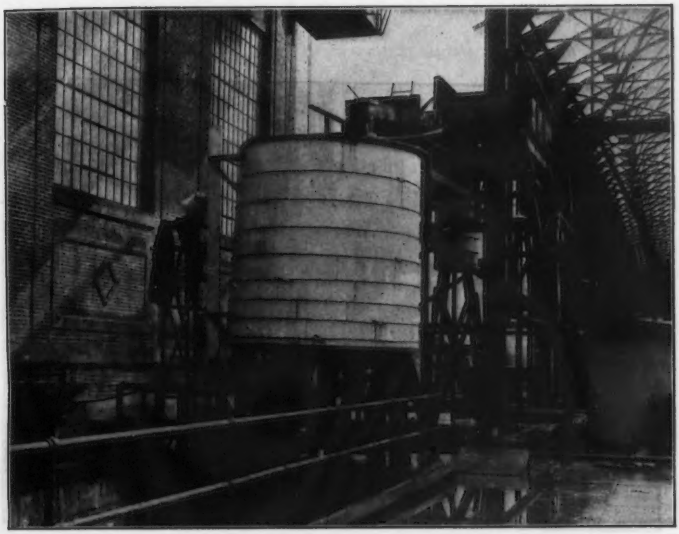

FIG. 18.—SALT-SOLUTION TANK, AND OBSERVER RECORDING READINGS OF SALT-SOLUTION GAUGE.

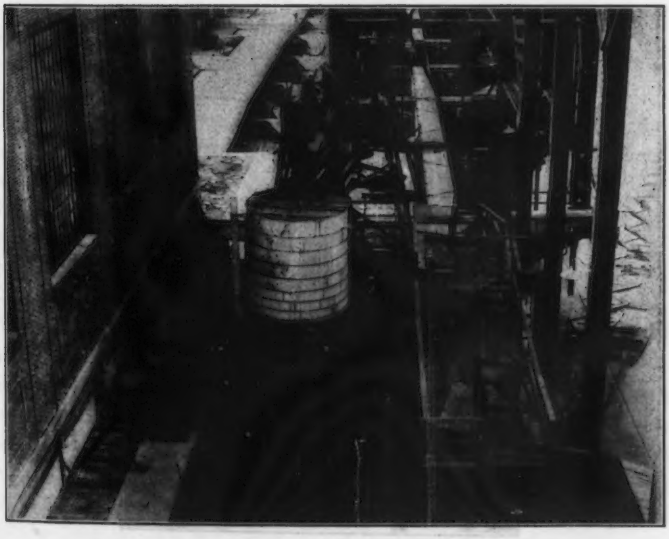

FIG. 19.—BIRD'S-EYE VIEW OF SALT-SOLUTION TANK AND DISSOLVING BOX.

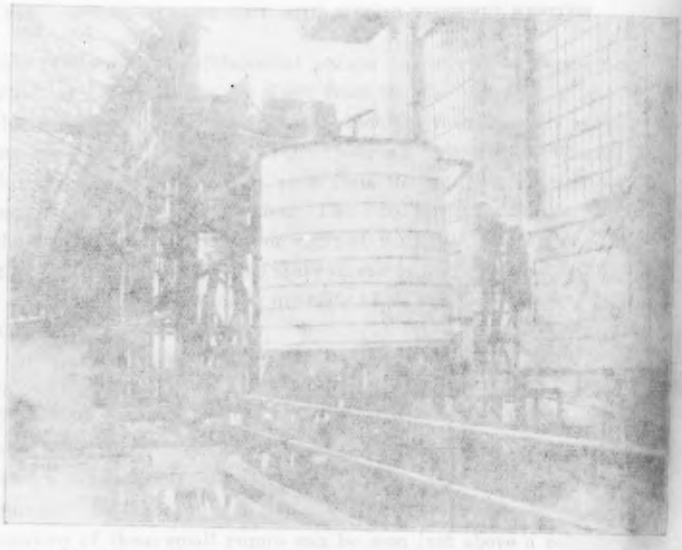

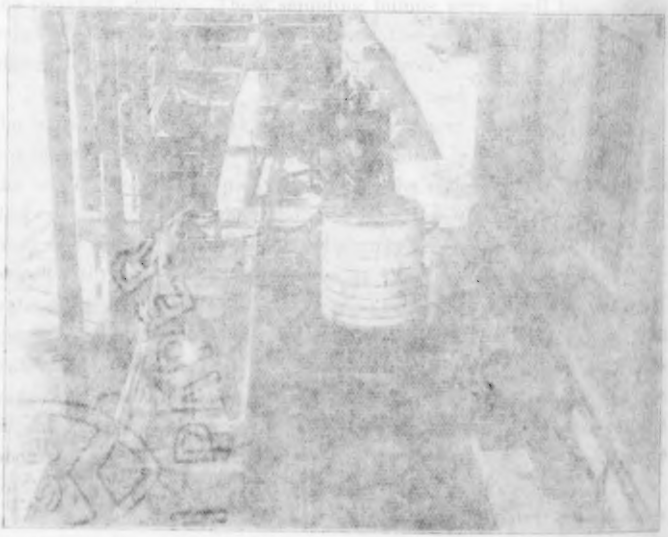

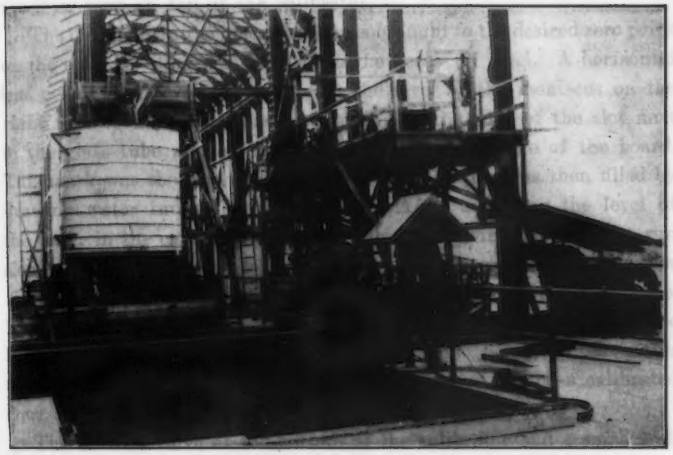

FIG. 20.—CENTRIFUGAL PUMP DRIVEN BY 75-H. P. MOTOR, AND 8-IN. DISCHARGE LEADING TO 8-IN. RISER AND HEADER ON PLATFORM.

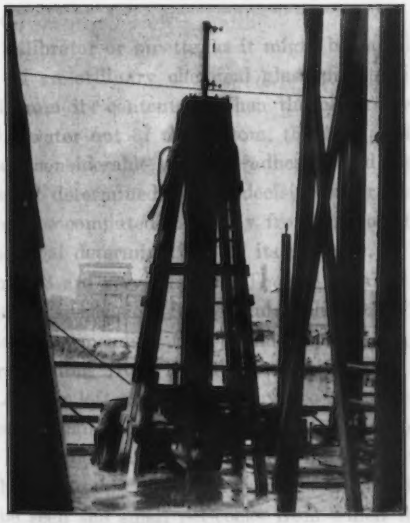

FIG. 21.—LARGE IRON CALIBRATOR. THE CONICAL TOP AND BOTTOM ARE NOT VISIBLE.

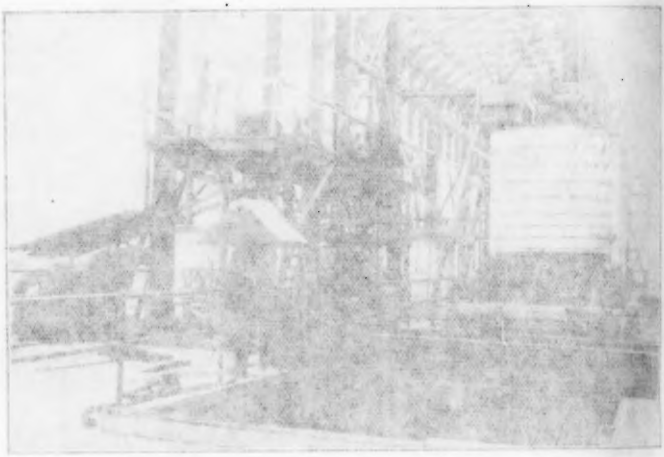

the salt-solution tank could be drawn by gravity through a hose into the 2-in. pipe on top of the calibrator.

The meniscus in the glass gauge was brought to the desired zero point on the scale by filling the tank up to the necessary level. A horizontal lead-pencil mark was then made at the level of the meniscus on the right face of the gauge-board, beginning at the edge of the slot next to the glass tube and extending toward the outer edge of the board. This mark was the zero graduation. The calibrator was then filled by drawing water into it from the tank. After adjusting the level of the water in the calibrator very carefully by allowing the water to run slowly from the tank into the calibrator, when nearly full, another mark was made at the lower level of the meniscus in the glass tube. The calibrator was then emptied by opening the throttle valve at the bottom, the water supply from the tank, of course, being cut off. After this the process was repeated until the gauge-board had been calibrated down to the desired limit.

The throttle valve at the bottom of the calibrator had a small leak which was taken care of by slipping a bottle under the calibrator so as to capture the water which escaped by drops. By pouring this captured water back into the calibrator at the proper moment the error was eliminated.

This large calibrator or pipette, as it might be called, possessed the characteristic of an ordinary chemical glass pipette, in that its delivery differed from its contents. When the calibrator is discharged by drawing the water out of the bottom, the sides and angles of the calibrator retain considerable water by adhesion and capillarity. This difference was not determined by any decisive experiments during the tests, but it may be computed indirectly from the results of the gravimetric and chemical determinations of its capacity.

Figs. 22 and 23 are very similar. They give fairly good views of the current-meter suspension frame and platform. The differential pulleys and cables suspending the sprinkler system may be seen, and also the risers leading from the 6-in. header on the deck over the framework. At the left center one may see the gate-valves on the risers, the pressure gauges and elbows connecting by means of nipples with the 2-in. hose pipes which form the flexible joint between the rigid header and the adjustable sprinkler system. On the bottoms of the nipples may be seen the small pet-cocks from which the salt-solution

samples were taken when it was desired to ascertain how uniformly the salt solution was being distributed by the 8-in. centrifugal pump. There were twelve of these sampling cocks, and, as has been previously stated, the samples taken therefrom were absolutely uniform in all tests made for the purpose of studying the distribution of salt solution among the twelve risers.

The table on which the five current-meter observers made their records is in place, and the telephone, enabling communication with all the other observers connected with the test, is at the lower right center just above the right end of the table.

Figs. 22 and 23 give a better view of the layout of the 8-in. discharge, 8-in. riser, and 6-in. header than any of the other illustrations.

Fig. 24 shows the discharge from the uppermost sprinkler when slightly raised above the surface of the water in the head-race. It will be seen that there is a system of holes discharging vertically upward, another discharging horizontally up stream and a third discharging vertically downward. Each of the six sprinkler pipes was perforated in this manner, so as to give as perfect a mixture in the head-race as possible.

The scaffold, on which one of the engineers may be seen, was arranged for the purpose of facilitating the current-meter work. It was found more convenient to attach and displace the meters when working on this platform than to attempt to raise and lower the meter rack through the gate-slot in the floor of the gate-house. The current-meter rack may be seen immediately back of the platform.

Fig. 25 shows the current-meter rack carrying the five current meters, as in a regular test. The rack is raised sufficiently to elevate the meters above the water surface.

Fig. 26 shows the battery of eighteen tail-race sampling pumps connected to the frame to which was attached the gear driving the cross-head which actuated the plungers of the pumps. The gears were driven by a 5-h.p. motor belted to the pulley shown at the top. Nine of the pumps discharged toward the observer and nine in the opposite direction, so that nine bottles were placed on one side of the pumps and nine on the other. These sample bottles were placed on a board provided with cleats to prevent the bottles from slipping. One of these boards can be seen in the lower foreground connected with two levers. This device was used to shift the bottles simultaneously from under

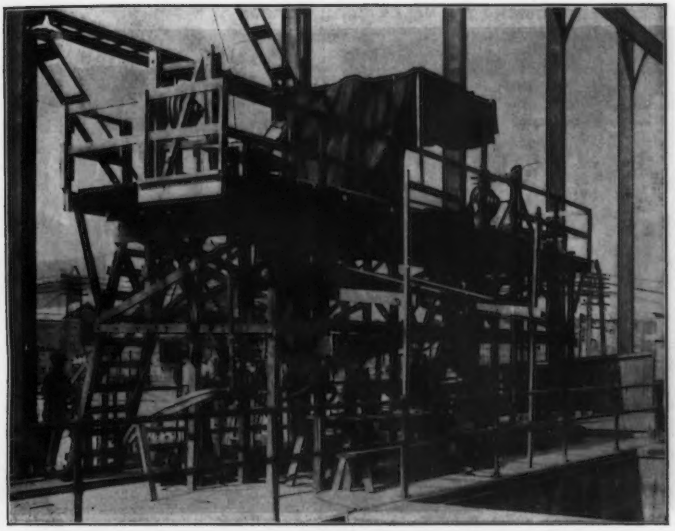

FIG. 22.—CURRENT-METER SUSPENSION FRAME AND PLATFORM, WHICH ALSO CARRIES THE DISTRIBUTING-PIPE SUSPENSION SYSTEM AND THE 6-IN. HEADER.

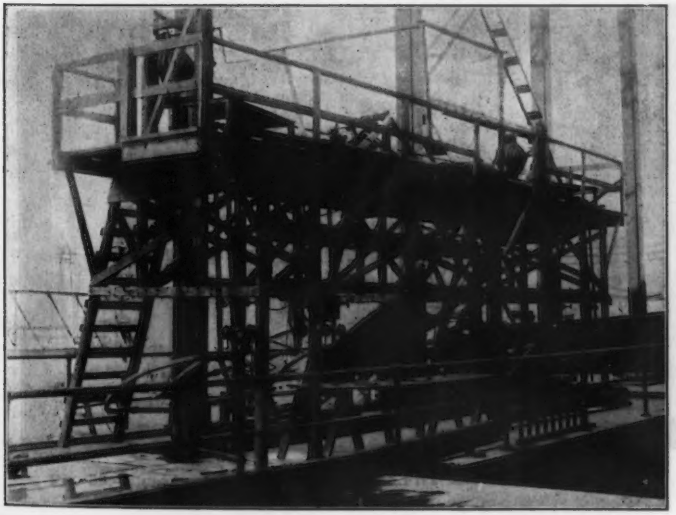

FIG. 23.—CURRENT-METER SUSPENSION FRAME AND PLATFORM.

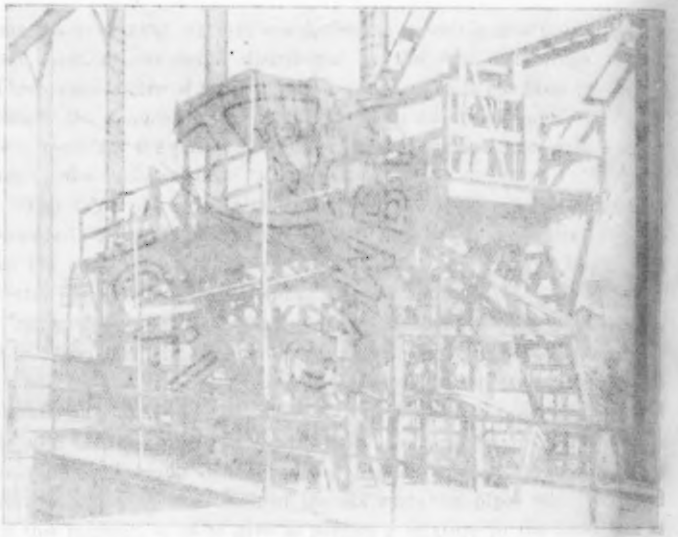

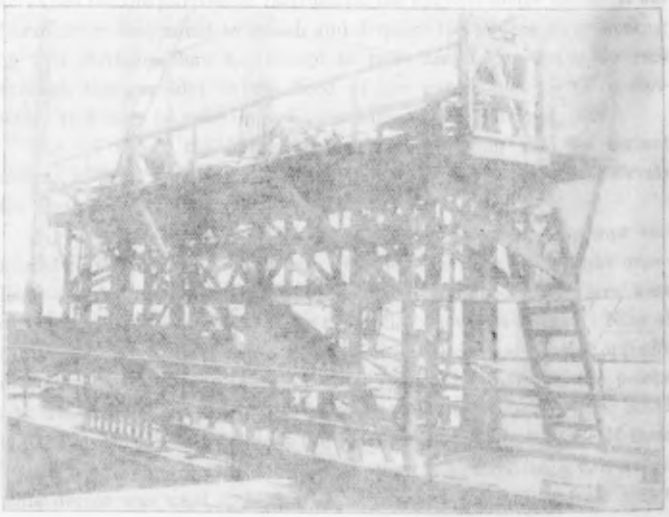

FIG. 24.—DISCHARGE OF UPPERMOST SPRINKLER OF SALT-DISTRIBUTING SYSTEM.

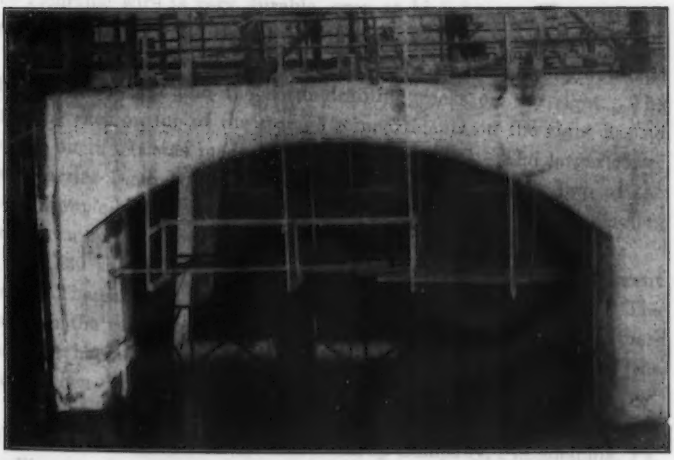

FIG. 25.—CURRENT-METER RACK, CARRYING FIVE METERS READY FOR TEST.

the discharges of the pumps when it was desired to stop the sampling. The levers were shifted in the opposite direction when it was desired to start the sampling. One attendant on each side of the battery of pumps took care of the sampling and watched the filling of bottles and the operation of pumps, so as to correct any interference with the proper taking of samples due to the failure of a pump or overflowing of a bottle.

Prior to the time of starting the samples, the attendants gauged each of the pumps, so that each bottle would be three-fourths full by the end of the test. The bottles were of the ordinary 1-gal. spring water type.

Fig. 27 shows the battery of separatory funnels and water-baths carrying the casseroles into which the separatory funnels discharge when the attendant opens the valve slightly so as to admit a small quantity of sample into a particular casserole.

The water-baths were heated by especially constructed electric heaters, the electrical switches for which may be seen on the wall back of the water-baths.

Fig. 28 shows one of the asbestos-board trays made to suport a 14 by 28-in. water-bath over the coil of nichrome resistance wire shown in the bottom of the tray. These heaters were very satisfactory, and the nichrome wire is very durable, even at high heats. The writer is indebted to Mr. G. K. Herzog for this design.

Fig. 29 is a view in the laboratory, showing the sample-storage shelves on the left and the bottle-draining racks on the right. The draining rack on top of the storage compartments on the right has no bottles on it. It was made for 1-qt. cream bottles. The larger lower rack carries 1-gal. bottles, a few of which are in place. Two of the 1-gal. sample-bottle carriers and one of the 1-qt. bottle sample carriers are shown on the floor below the draining rack.

Fig. 30 shows the large shunt used in testing the direct-current units. The shunt is in place as it was attached to Unit No. 12. The basin in the center of the shunt contains kerosene into which a thermometer hangs for the purpose of furnishing the temperature of the shunt when desired.

This shunt is of peculiar construction, and was designed by Mr. I. B. Smith, of the Leeds and Northrup Company, Philadelphia, Pa.

Fig. 31 shows the voltmeter and ammeter potentiometers which

were used in determining the direct-current electrical power across the shunt, shown in Fig. 30, and between the terminals of the generator. These instruments were also manufactured by the Leeds and Northrup Company. They are extremely sensitive, and the direct-current power readings are very accurate, probably being within 0.1% of the truth. The instruments are even more accurate than this under laboratory conditions.

PART IV.

THE TESTS.

93.—Tests on Unit No. 13.—The tests on Unit No. 13 may be divided into three series. The first is indicated by letters instead of numbers. The second comprises the tests bearing numbers from 1 to 25, inclusive, and the third comprises all the remaining numbers. Certain tests which were not turbine tests have been given letters, or numbers, and these letters or numbers, therefore, are not in the tables or on the diagrams connected with the turbine tests proper. In all cases the tabulations of turbine tests give them in consecutive order, whether the numbers, or letters, appear consecutively or otherwise.

The first series (letters) comprises the preliminary tests which were made while the corps of observers was becoming familiar with its work, and before the high-precision electric instruments were inserted in the circuit. In this series the tail-race samples were taken from the lower, or stop-log-slot, sampling section, excepting Samples 41 and 42, which were from the centers of the upper and lower draft-tubes on the upper sampling section, which was a vertical section in the plane of the Pitot tube pipes extending into the tail-race just down stream from the discharge ends of the draft-tubes. Sample 43 was usually taken from the center of the upper sampling pipe on the lower section, but could be taken from any other position in the tail-race.

The tests of the second series (Nos. 1 to 25) were executed in a manner similar to those of the first, but were made immediately after inserting the high-precision electric measuring equipment, and, therefore, are to be regarded as more accurate than those of the first series.

The tests of the third series were made after moving the tail-race sampling system from the lower to the upper sampling section, and after increasing the number of regular tail-race samples from 12 to 18, but cutting out the extra samples, Nos. 41, 42, and 43.

The lettered tests, therefore, relate to preliminary work, before accurate power measurements were made, and the numbered tests relate to those in which accurate power records were taken by high-precision instruments. The tests bearing numbers higher than 25 were those during which the tail-race samples were taken from the upper sampling section, and are the most accurate of any.

The object in moving the tail-race sampling system from the lower to the upper section, after the second series, was to secure more reliable samples and a larger number of them. The principal reason for this change was the fact that the risers leading to the sampling pumps had to pass up through several feet of water which was more or less diluted by water from other turbine units not being tested. Should any of these risers leak it would be likely to take in water which did not contain a sufficient quantity of salt or, at least, did not come from the location at which it was intended to secure a sample.

99.—Tests on Unit No. 12.—There was only one series of tests on Unit No. 12, numbered from 200 to 212, inclusive. They were executed in consecutive order, from September 28th to October 13th, 1914, and cannot be considered as good as the third series on Unit No. 13. This is due to the less favorable weather conditions, to changes in personnel of observers and manipulators, and also to the fact that the hydraulic conditions of the tests were not so uniform and satisfactory. In particular, the power measurements are not as satisfactory as those on Unit No. 13, and this is probably due to the fact that the power was observed and the electrical instruments manipulated in the latter case by Mr. I. B. Smith, the designer of the instruments.

100.—Tests on Unit No. 11.—There were two series of tests on Unit No. 11. The tests were started with No. 105, on September 12th, but after running four more tests, ending with No. 109, on September 18th, it became necessary to shut down the unit for repairs, and there were no more until November 9th, when Test 111 was made. This second series was then continued consecutively up to 122 on November 21st, which ended the series, and in fact all the turbine tests.

The generator of this unit was of the alternating-current type, and those of Units Nos. 12 and 13 were both of the direct-current type. Consequently, an entirely new set of electrical measuring instruments was required, with additional observers, and correspondingly more difficulty in securing data. The power records, however, are very consistent, under the circumstances, and approach in accuracy those of the best tests on Unit No. 13.

101.—Field Data.—Tables 46, 47, 48, and 49,* contain a summary of all the field data observed during the entire series of turbine tests,

* These tables are not reproduced in this paper, but are filed in the Library of the Society for reference by any one interested.

exclusive of the data necessary for the chemical work proper. As a general rule, all instrumental readings given on these sheets are averages computed from numerous readings taken at the end of equal intervals of time, with the maximum variation during the entire test recorded immediately after the corresponding averages.

The method of measuring the head was specified in the contract, but a slight divergence therefrom was agreed on, owing to the difficulty of measuring the head-water exactly 5 ft. down stream from the racks at the water surface. This difficulty arose from the fact that the gauge-boards would have been somewhat inconveniently situated at that exact distance in all the tests, as the distance to the gauge-board from the racks at the water level varied considerably with changes in elevation of head-water due to the slope of the racks. At surface elevation 197 the location of the gauge-boards was just about as specified in the contract.

The principal head-water readings, however, were made by measuring downward at three points across the head-race from an angle iron which was fixed at Elevation 204. The scales on the measuring rods were inverted, with the 204-mark at the bottom of the rod, so that, by holding the bottom of the rod in contact with the water surface and reading the inverted scale on the rod at the edge of the angle iron, the true elevation of the water surface was ascertained without further correction.

As a matter of convenience, the rods passed through holes in the flat side of the angle, so that by boring holes the size of a nail at various points along the rod and then inserting a nail in the hole nearest to the proper graduation mark, the rod could be left by the gauge reader to swing loosely at about the correct elevation, thus being ready for use at any time without the necessity for much adjustment.

The three rods and the two gauge-boards gave the elevations of the water surface at five points in the head-race. The distances between these five points were not exactly equal across the race, owing to the desire to obtain readings of the two rods adjacent to the center rod, which would indicate the surface elevation back of the two rack girders where the water surface was relatively low.

The tail-water elevation was observed in much the same manner, there being two gauge-boards at the side-walls and three rods manipulated in a manner similar to that used in the head-water readings. The

three rods, however, were just outside the power-house, in the center-line of the three openings of the tail-race formed by the two side-walls and the two tail-gate girders. The rods, therefore, were equally spaced on each side of the rod at the center.

There was also a float-gauge in the head-race, at the inside of the west rack girder, and one in the tail-race at the west wall. These floats did not give accurate results because of the influence of the velocity heads created in and around the gauge-board box. Probably more accurate results could have been obtained by a further study and re-arrangement of the float-gauges.

The output of Units Nos. 13 and 12 was measured by three different sets of direct-current equipment. The first set consisted of the ordinary switch-board instruments; the second consisted of high-precision instruments purchased from the Leeds and Northrup Company, and the third was a Weston outfit, furnished and operated by the Allis-Chalmers Company for its own information.

In the tests of Unit No. 11 there were also three sets of instruments. The current in this case, however, was 25-cycle, at about 2 200 volts, thus limiting the tests to a fixed speed which exceeded 100 rev. per min.

The first set was the switch-board equipment; the second was a high-precision Weston outfit purchased for the purpose, and the third was the Allis-Chalmers' Weston outfit.

The speed of the turbine was taken by a tachometer, and checked by actual count.

The tables show the data for the salt solution, the temperature of the solution in the tank, the concentration computed from the hydrometer reading, the two pairs of divisions on the gauge scale between which the surface of the solution stood at the start or finish of each test, the time of passing these divisions, the time of starting the salt-solution discharge, the time when the discharge was adjusted and uniform, and the time of starting and finishing the test.

The pressures at which the distributing pipes were operated are given, but it must be understood that these are mere readings of gauges on the sides of the pipes. These gauges had not been calibrated, and were subject to the usual errors when attempting to secure pressures from pipes inserted in the side of another pipe in which the pressures are to be estimated. The gauges, however, served their pur-

pose well in supplying a means for controlling the distribution of salt in the head- and tail-races.

There is also a column for remarks at the right of each of the data tables.

102.—Tables of Observed Concentrations.—Space will not be devoted to the detail of all the concentrations observed in all the tests. If it is desired to examine the detail of any test, which is not fully supplied in this paper, the original data are on file, and access will be furnished by the writer.

The four principal series of titrations, however, given in detail in the next four sections, furnish a complete exhibit of the best of the chemical work.

In the case of Units Nos. 12 and 13, and the first series of tests on Unit No. 11, the strength of the silver nitrate solution was about 1.56 grammes per liter. In the case of the second series of tests on Unit No. 11, in fact, the last of the turbine tests, the strength was about 1.45 grammes per liter, resulting approximately from the solution of 1.45 grammes in 1 liter of distilled water.

As a general rule, the tests were titrated the day after they were made, the evaporations having been made over night in the laboratory, which operated continuously. The second treatments of certain of the tests, usually indicated by the letter *B* affixed to the regular test number, are exceptions to this rule. They were made long after the first treatments, and the results show that the samples suffered more or less from reductions of volume due to evaporation during the interval.

This experience indicates that extraordinary care must be taken to preserve samples, when they are to be kept for any length of time before treatment. One-quart large-mouthed cream bottles with paraffined cork stoppers will not do for this purpose.

103.—Concentrations Observed During Eleven Consecutive Tests on Unit No. 13.—The dilute salt solution is prepared by diluting one 10-c.c. pipette of salt solution to the graduation mark of a 1-liter flask with distilled water, 10 c.c. of this dilution then being taken for titration. In all cases $\frac{1}{2}$ liter of normal head-water and $\frac{1}{2}$ liter of tail-water are evaporated to about 10 c.c. in a casserole for titration. Titrations in parentheses have been omitted from the calculations as doubtful. The unit of titration is $\frac{1}{100}$ c.c., all decimal points being omitted except in the final averages, where the unit is 1 c.c. The

capacities of the pipettes and flasks mentioned are nominal; the actual capacities may be determined by Figs. 4 and 6. In all cases, Pipette No. 18 791 was used on strong salt solution, and Pipette No. 21 047 on dilute salt solution; and Flasks 1 456 and 1 476 were used on dilution of salt solution. Flask No. 11 was used for measuring normal head- and tail-water in all cases except Test 32, on which Flask No. 3 was used. Missing test numbers represent tests which were not chemical. The chemical tests follow in the consecutive order in which they were made.

CONCENTRATIONS OBSERVED DURING ELEVEN TESTS ON UNIT NO. 13.

Titrations in parentheses have been omitted as doubtful. The unit of titration is $\frac{1}{1000}$ c.c., all decimal points being omitted except in final averages, where the unit is 1 c.c.

106.—Concentrations Observed During the Second Series of Tests on Unit No. 11.—The dilute salt solution is prepared by diluting one

10-c.c. pipette of salt solution to the graduation mark of a 1-liter flask with distilled water, 10 c.c. of this dilution then being taken for titration. In all cases ½ liter of tail-water and ½ liter of special dilution are evaporated to about 10 c.c. in a casserole for titration. Titrations in parentheses have been omitted as doubtful. The unit titration is $\frac{1}{1000}$ c.c., all decimal points being omitted except in the final averages, where the unit is 1 c.c. Capacities of pipettes and flasks mentioned are nominal; the actual capacities may be determined by Figs. 4 and 6. Flask Nos. 1 407 and 1 457 were used for dilution of salt solution on all tests except Test 117, in which Flasks Nos. 1 407 and 1 476 were used.

	5 435			5 428		5 410	

Flasks Nos. 1 407 and 1 457 were used for special dilutions in all tests. Pipettes Nos. 9 171 and 9 206 were used on strong salt solution, dilute salt solution, and stock solution. No normal head-water was evaporated. The methods of making the solutions are explained in the rules for the chemical laboratory at the end of Part II. See Sections 88 and 89.

107.—Discharge Computations.—Tables 50, 51, 52, and 53 (Plates XLI, XLII, XLIII, and XLIV), contain all the data necessary for the chemical determination of the discharge in the various tests. These calculations have been carried out with more refinement, in certain respects, and more elaborately, than necessary. This is especially true when these methods are compared with the simple one of weighing samples, explained in Sections 10 to 18, and applied in Section 78 to the determination of the capacity of the iron calibrator.

In view of the full explanation of the theories and equations given in Parts I and II, it will not be necessary to enter into a detailed explanation of the nature of the discharge computations, which are, in fact, quite fully explained by the tables.

←——Long Marks (1st Calibration) on Gauge Board of Salt Solution Tank Used on These Tests.——→

Note.—Missing Tests, *A, D, E*, represent rough preliminary tests by chemicals, and are not included in this table. All other chemical tests appear in the tables in the order in which they were executed; missing numbers, or letters, relate to tests by current meters or to tests for purposes other than turbine performance.

Missing Tests, *B, C, F, J, P, Q, R*, 1-5, incl., represent current-meter tests.

Missing Test, *M*, represents a distribution test.

No Leeds and Northrup or Allis-Chalmers power readings taken on lettered tests. (High-precision instruments.)

Some of the discharges are more or less questionable owing to the probability of leaks in the tail-race sampling pipes. In computing this table, titrations of doubtful samples have been omitted, figures being substituted instead, which are based on the titrations of adjacent samples. The table on the right gives the discharges of Tests 5, 10-13 incl., using the actual titrations, no alterations, or substitutions, being made. These are the only tests thus treated as being doubtful in this series.

*In Tests 7 and 9 the salt solution samples were undoubtedly interchanged by mistake in the laboratory. More correct values for the discharge in these tests can be computed by interchanging the values given above for v and recomputing Q_2. Thus, for Test 7, $Q_2 = 1\,668$, and for Test 9, $Q_2 = 1\,712$.

OR COMPUTATION OF TURBINE DISCHARGE. COMPILED FROM RECORDS OF TESTS MADE ON UNIT NO. 13, JULY 18TH, 1914, TO AUGUST 19TH, 1914.—

←——Long Marks (1st Calibration) on Gauge Board of Salt Solution Tank Used on These Tests.——→

←——Sampling Pipes on Lower

NOTE.—Missing Tests. *A, D, K*, represent rough preliminary tests by chemicals, and are not included in this table. All other chemical tests appear in the tables in the order in which they were executed; missing numbers, or letters, relate to tests by current meters or to tests for purposes other than turbine performance.

Missing Tests, *B, C, F, J, P, Q, R*, 1-5, incl., represent current-meter tests.

Missing Test, *M*, represents a distribution test.

No Leeds and Northrup or Allis-Chalmers power readings taken on lettered tests. (High-precision instruments.)

Some of the discharges are more or less questionable owing to the probability of leaks in the tail-race sampling pipes. In compiling this table, titrations of doubtful samples have been omitted, figures being substituted instead, which are based on the titrations of adjacent samples. The table on the right gives the discharge of Tests 8, 10-13 incl., using the actual titrations, no alterations, whatever, being made. These are the only tests thus treated as being doubtful, in this series.

*In Tests *T* and *U* the salt solution samples were undoubtedly interchanged by mistake in the laboratory. More correct values for the discharge in these tests can be computed by interchanging the values given above for v and recomputing Q_2. Thus, for Test *T*, $Q_2 = 1\,603$, and for Test *U*, $Q_2 = 1\,813$.

Sampling pipes on upper section.

olution tank used on these tests.

There is, therefore, some doubt as to the accuracy of 38 *B*. It would be better, perhaps, to disregard the *B* tests entirely.

Tests 34, 35, 37-41, incl., and 44-53, incl., represent current-meter tests. Some of the discharges, Tests 15-21, incl., are more stionable, owing to the probability of leaks in tail-race sampling pipes. In compiling the above table, titrations of mples have been omitted, figures being substituted, which are based on the titrations of adjacent samples. The table on es the discharge of Tests 15, 17-21, incl., using the actual titrations, no alterations, whatever, being made.

§ The titrations of tail-water samples in Test 45 *B* were made about a week after Test 45. They indicate that the samples had become contaminated, one of them being 72.45 c.c., as against about 54 c.c., the correct value. This reduction of Test 45, consequently, is disregarded.

TEST 206, OCTOBER 6TH, 1914.

TITRATION, OCTOBER 7TH.
Nitrate (1.56 grammes), October 5th.

It may be repeated that the tests are entered in consecutive order in the tables exactly as they were made in the field, the missing numbers, or letters, relating to other than regular turbine tests. Such, for example, are Tests *M*, which consisted of a series relating to the distribution of salt in head- and tail-races.

The concentrations of salt solution, normal head-water, special dilution, and tail-water are, of course, the mean values computed from the titration tables, Sections 103, 104, 105, and 106, or from similar tables on file as explained in Section 102.

In the case of the salt-solution, normal head-water, or special dilution samples, the simple arithmetical mean has been used, sometimes cutting out titrations which were questionable. The particular titrations thus cut out are enclosed in parentheses in the tables of titrations.

In the case of the tail-water, the weighted mean for the average titrations of the four quarters of the draft-tube has been used, the weights being determined from Figs. 37, 38, and 39. These weights are merely the four relative mean velocities for the four quarters of the draft-tube, as determined by the Ott current meters, uncorrected for their deviations from the still-water ratings.

Where the normal head-water has been titrated directly, a correction for the error of such a titration, as explained in Section 43 *et seq.*, has

TABLE 53.—Data for Computation of Turbine Discharge. Compiled from Records of Tests Made on Unit No. 11, Nov. 9th to Nov. 21st, 1914. See Table 52 for First Series of Tests on

$= h v_1$
$= V_1$

Value of v_1 is not given and was computed from Test 130 A as follows: $v_1 = \frac{E' v'_1 - v}{r}$ or $v_1 = \frac{6\,938.2 \times 114.478 - 598\,937}{6\,938} = 25.35$. Then $E' = \frac{594\,904 - 0.97 \times 25.33}{118.699 - 25.35} =$

Weighted mean = 50.641

The pipette and flask calibrations are given in Figs. 4 and 6, respectively.

108.—Tests on Which Special Dilutions Were Used.—No special dilutions were used in the tests on Unit No. 13, except in the second treatments of Tests 23 and 26. In all the tests on Unit No. 12, and in the first series on Unit No. 11, special dilutions and normal head-water samples were both used so as to show that the corrections computed in Section 43 give accurate results when applied to normal head-water titrations. A comparison of the simultaneous results by the two methods is given in Section 86.

No normal head-water samples were titrated in the second series of tests on Unit No. 11.

109.—Final Computations.—The final computations, individually unadjusted except as to the calibrations of instruments and corrections indicated in the various tables, appear in Tables 54, 55, 56, 57, 58, and 59.

Table 54, Unit No. 13, First Series.—This is for the first, or lettered, series of tests on Unit No. 13. These tests are quite accurate as to discharge measurements, but cannot be regarded as anything but

preliminary tests for the purpose of adjusting the apparatus and training the corps of observers. The power was measured on the switchboard instruments only.

TEST 111, NOVEMBER 9TH, 1914.

TITRATION, NOVEMBER 10TH.

Nitrate (1.45 grammes), November 6th.

It should be remarked that Test 39 has been interpolated. The head-water elevations were lost, and, unfortunately, there was an unusual variation in this respect during the test. This was a disappointment, as it would have been desirable to know what degree of consistency such a test would show, as compared with those made under more favorable conditions. As it is, very little weight should be at-

the power measurements may be attributed largely to a change in the personnel of the power observers and manipulators, and to the greater haste necessary in order to complete the work within the time limit of 2 weeks for this unit. The discrepancies in the discharge measurements result largely from uncertainties as to the proper weights for the various tail-water concentrations, which become relatively more

† Value interpolated.

important for Unit No. 12 owing to the fact that the hydraulic conditions of the tests were not so uniform nor so satisfactory, from the standpoint of turbine driving. The efficiency is markedly less for this unit than for Unit No. 13, and this may be attributed to the relatively higher degree of turbulence of the head-water. It can scarcely be doubted that turbulence in the head-water has an effect on the efficiency of a water-wheel, though this would probably be small, relatively. Tests to ascertain the truth or falsity of this proposition are highly desirable.

Table 58, Unit No. 11, First Series.—These tests were started on September 12th, 1914, but it was found necessary to shut down for repairs on September 17th, before there had been time to get the equipment adjusted. Test 105 is wholly untrustworthy, as the governor was not blocked and the gate varied over a large range. The power was absorbed by a large water-rheostat, but this was improperly placed in the tail-water, which varied in elevation from moment to moment, thus changing the load and causing the variations of gate mentioned. The load was also affected by variations of salt content in the tail-water. The rheostat was not used in any test after the first one, Test 105.

The writer is not an advocate of rheostat tests for efficiency trials of hydro-electric units in place. It is very true that a uniform load can be secured in this way, but it is far better to secure tests under actual operating conditions. That such tests can be accurately conducted on either direct or alternating circuits is amply proved by the whole series which form the subject of this paper. Moreover, it is demonstrated herein that considerable variations of load do not affect seriously the results of a test which is properly conducted, especially if such variations are restricted within certain limits. One such test will check another under similar conditions of equal average load with surprising exactness.

Table 59, Unit No. 11, Second and Last Series.—These tests are more satisfactory than those on Unit No. 12, but not so good as those on Unit No. 13. When corrected for speed variations, the results agree very consistently, except in the case of Test 122, which must be discarded entirely. In preparing for this test it was found that all the available sample bottles were full from other tests. Accordingly, some bottles which had been set aside with salt solution were rinsed out and

used, but the tail-water samples show conclusively that the bottles were not sufficiently cleansed. Some of the samples titrated nearly twice as high as they should. Certain samples, however, had the appearance of being about right in respect to their salt content, and the test has been worked up on this basis, with the result that the final figures are not far from the truth, but the facts rob the result of any intrinsic value. Test 118 seems to agree with Test 122, but an inspection will show that there was considerable difference (3 rev. per min.) in speed. The tests, therefore, are not directly comparable.

110.—Plottings of the Tests.—The final adjustment of the tests for the purpose of determining turbine efficiencies cannot now be made, as the efficiencies of the generators are not known for the various conditions of performance. The over-all efficiencies of the units, however, would appear to be well determined by the curves which may be drawn with reference to the final computations, Section 109.

Plate XLV, Unit No. 13, First Series.—These were the lettered tests in which the power was measured by the switch-board meters only. Although the discharge measurements were made with considerable accuracy, there is a strong probability that some carelessness in the laboratory resulted in the interchange of salt-solution samples for at least one pair, and possibly two pairs of tests. The most questionable pair in this respect is *T, U,* where an interchange of salt-solution samples would make better harmony as regards results. The fact which lends weight to this view is that at about this time the salt-solution samples were, on several occasions, titrated on the morning following the titration of the other samples for the same test—a procedure which is strongly to be condemned. Tests *T* and *U* are subject to this suspicion. They would be far more harmonious if the salt-solution titrations were interchanged in the calculations, as may be seen by an inspection of the data and results.

The power on these lettered tests may be rendered comparable with the later series by applying a correction to the switch-board instruments.

Plate XLVI, Unit No. 13, Second Series.—In this series, computed in Table 55, Section 109, the tail-race samples were taken principally from the lower sampling section. It has been mentioned that some leaks were discovered in the risers for these samples at points where

														Ave.=	62.333	used on this series of tests.

General Notes.—This unit generates direct current. The flow of salt solution was not stopped between Tests 7 and 8, 13 and 14, 15 and 16, 17 and 18, 20 and 21, and each pair of tests was run in immediate succession. "East and West Dosed Tail Samples Mixed" means that each sample taken on the east side of draft-tube was mixed with its corresponding west sample taken at same elevation. Thus there were half as many samples to titrate as were actually taken out of the draft-tube.

In these tests the power was measured by the high-precision, direct-current instruments, and was very satisfactory, but there was some question as to the tail-water samples during some of the tests, owing to the discovery of leaks in the sampling pipes in the lower section at the elevation of river water above the tail-water proper. The upper figures in discharge and efficiency columns, are results obtained by taking titration of doubtful samples as correct. The lower figures are obtained by omitting the titration of doubtful samples, values being substituted, instead, which are based on the titration of adjacent samples.

Dosed tail-sampling pipes on lower section. Eight samples on upper section also in Test 19. Gate locked on all tests.

Discharge obtained by method of unbalanced evaporations.

contamination would be likely to occur. Hence, in computing Table 55, the titrations of the samples which appeared to be too low were at first corrected by cutting them out and inserting the averages of some of the adjacent samples in their places. The next diagram gives a plotting of the tests without any arbitrary corrections, and these check the third series even better than the plottings of the diagram now in question.

Tests 6, 9, 10, 11, 12, and 19 are the only ones of this series in which the tail-water samples were titrated in complete detail. In all the remaining tests the twelve regular tail-water samples were combined in pairs, by mixing equal parts of each one of every pair of samples, thus reducing the number of titrations for these samples from twelve to six. The small number of samples, however, is not the worst feature. The main trouble is that, with so few samples, it is not possible to correct for non-uniformity of distribution with any degree of certainty.

It is also to be observed that these particular tests were intended to cover a larger range of speed variations than was permissible under the terms of the contract. It was hoped by the writer that enough material could be accumulated in this way to diagram the wheels. Unfortunately, the representatives of the Allis-Chalmers Company did not agree unreservedly to such a plan, and it was necessary, therefore, to confine the work as closely as possible to the contract conditions of 100 rev. per min. On account of these speed variations, coupled with the uncertainties as to distribution of salt in the tail-race under such conditions, especially in the case of the partial tests just mentioned, it must not be expected that the points for the tests will plot in a smooth curve.

Test 19 of this series, and Tests 22 and 23 of the next, or third, series are worthy of particular notice, as the full quota of twelve samples was taken at the lower section while eight well-distributed samples were taken in the upper section, about 8 ft. farther up stream, and well away from any influence of unsalted tail-water. These were the last tests for which any samples were taken in the lower section. This was on account of the difficulty of maintaining the sampling system there, so as to prevent leaks in the pipes. Tests 20 and 21 were merely partial tests, as explained. After cutting out one sample on the lower section in Test 22 and three in Test 23, on account of breaks in the correspond-

Tests 22-46, incl.
Over-all Efficiency, in Percentage.
Discharge, in Cubic Feet per Second (Based on 30 Ft. Head).

ing pipes, Table 60 was compiled. It shows an interesting comparison of titrations of the two sets of samples in these tests.

TABLE 60.—Comparison of the Average Titrations from the Upper Sampling Section with the Average from the Lower Section.

(The averages are from eight samples on the upper section and twelve on the lower, except that one sample on the lower section for Test 22, and three for Test 23, have been suppressed on account of leaks in the corresponding pipes.)

Test 19.

	Upper Section.		Lower Section.	
	W.	E.	W.	E.
Upper half	58.41	58.07	58.22	58.30
Lower half	58.55	59.08	58.71	59.12
Means	58.48	58.58	58.46	58.71

Test 22.

Upper half	59.45	59.52	59.05	58.66
Lower half	57.65	57.90	58.20	58.10
Means	58.55	58.71	58.62	58.38

Test 23.

Upper half	60.89	60.72	60.26	60.12
Lower half	57.06	56.95	56.52	58.10
Means	58.98	58.84	58.39	59.11

Summary of Means.

Test.	Average upper section.	Average lower section.
19	58.53	58.58
22	58.63	58.50
23	58.91	58.75
Mean	58.69	58.61

From Table 60, therefore, it is apparent that there was no material difference between the concentrations from the upper and lower sta-

tions when the pipes on the lower station were in good condition. The small deficit of 0.08 c.c. in nearly 60.00 c.c. may be due to some slight leaks on the lower section which were not discovered, or it may be due to unavoidable errors in the work.

The tests of this series will appear to be more harmonious when compared with the Holyoke tests by using Plate LI.

Tests 8, 16, 17, and 18 are very doubtful as plotted. They were off-speed tests, but the principal cause of deviation from correct plotting is probably due to lack of data as to distribution of salt and relative weights. This applies to all the partial tests.

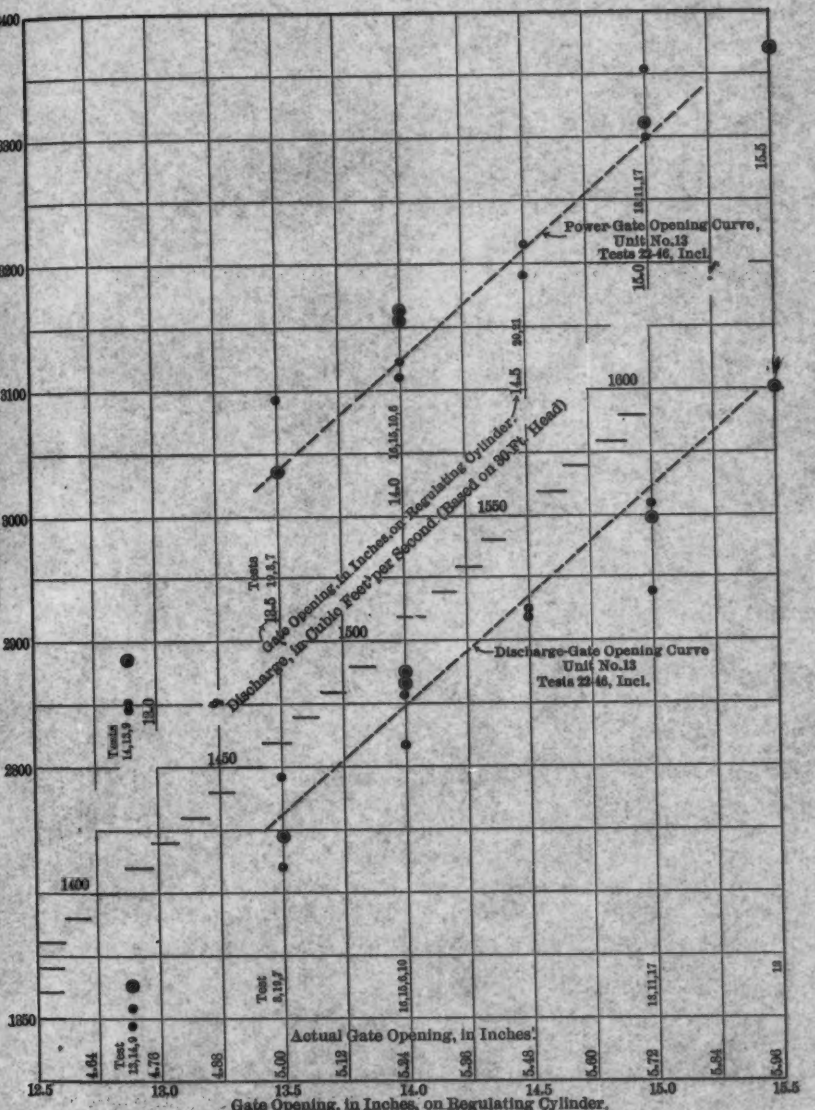
Plate XLVII, Unit No. 13, Second Series, Second Plotting.—After plotting this series, as on Plate XLVI, where certain tail-water samples were eliminated owing to supposed leaks, the tests were re-plotted, taking into account all the titrations as usual, without regard to the possibility of leaks. This plotting is shown on Plate XLVII, and it will be seen that the changes in main are small, but that the final plotting checks that of the third series even better than that of Plate XLVI.

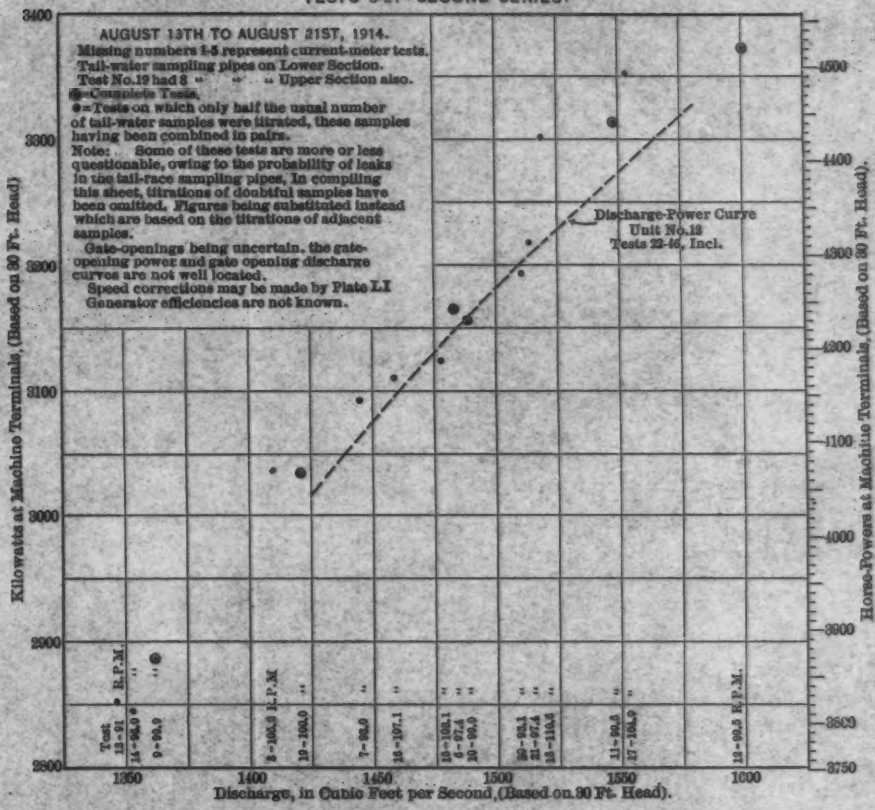
Plate XLVIII, Unit No. 13, Third Series.—This series is remarkable for its self-consistency and for the high degree of precision attained in so far as accidental errors are concerned. It has also been shown in Part II that there cannot be any serious systematic error in this series. In all probability, they are the most precise discharge measurements ever made on a hydro-electric unit of large capacity for water.

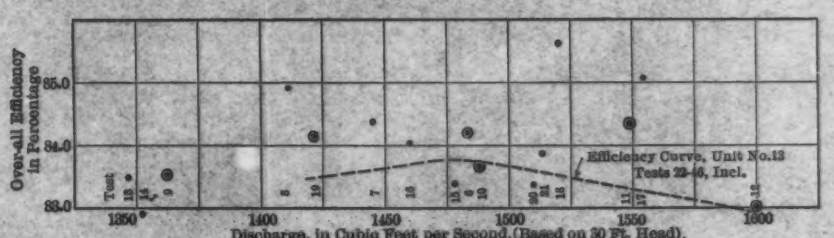
Test 39 is the only one about which there is any question. Unfortunately, during this test, the greater portion of the head-water observations was lost, thus taking away any opportunity for arriving at the correct head based on observation. The head has been interpolated so as to harmonize the test with the others. Had these observations been lost on any other test, the matter would not have been so serious, because, in Test 39, the head varied by 1½ ft. or more, and it was desirable to have the results of a test, under such conditions, but the only chance in this series was lost.

The close agreement between concentrations on the upper and lower sampling sections in Tests 22 and 23 has been shown in Table 60 in connection with Plate XLVI.

FINAL CURVES.
TESTS OF UNIT NO.13
TESTS 6-21 - SECOND SERIES.







Gate Openings.—No effort was made, in any of the tests, to secure accurate records of gate opening. The gates were calipered in the usual manner, and a curve connecting the actual opening with gate-register indications was drawn. These openings, as well as the corresponding gate-register readings, are plotted at the left of the plate, as in the preceding cases.

The method of setting the gate was always to open it from a relatively small opening to the one at which the test was to be run, thus avoiding the effects of back-lash as far as possible. It was quite possible, however, for the gate to move after being set, and it is very clear, from the diagram, that such motions did occur, and always in one and the same direction from the gate-power or gate-discharge curve. This would be the natural consequence of the method of setting the gate, and the consistency of the plottings in this respect adds materially to the weight of the statements concerning the accuracy of this series of tests.

The real precision of the tests comes into view when power and discharge are plotted against one another. An extremely accurate efficiency curve results by computation from this discharge-power curve, and it is seen that, of the plottings of the efficiencies from Table 56, only two or three of the thirteen fall away from the curve by as much as 0.1 per cent.

Plate XLIX, Unit No. 12.—This is the only series of tests on Unit No. 12. The plottings were made from the data of Table 57. Tests 209 and 211 are the only ones plotting seriously wild. Test 211 seems to be low on power, and 209 is high on discharge. Otherwise the tests leave no doubt as to the fact that Unit No. 12 is not so efficient as Unit No. 13. The fact that accidental errors are larger than for Unit No. 13 is due to the greater haste with which the tests were made and to several changes in the personnel of observers, the new men not being so well trained in their work. This is especially true of the power, which, however, is quite consistent with the Allis-Chalmers readings, excepting for Tests 211 and 212. In these two the Allis-Chalmers instruments are inconsistent with both the standard and the switch-board instruments, as the ratios in Table 61, computed by slide-rule, indicate.

The Leeds and Northrup and switch-board readings being the more consistent, it would scarcely seem that the power can be seriously in

error. It is more probable that the wild plottings result from an accumulation of small errors due to one cause or another. A further adjustment of the tests might be made, but this would not make any material change commensurate with the work necessary to effect a satisfactory adjustment.

TABLE 61.—COMPARISON OF THE RATIOS OF POWER READINGS FOR THE SWITCH-BOARD, ALLIS-CHALMERS, AND LEEDS AND NORTHRUP, DIRECT-CURRENT INSTRUMENTS IN THE TESTS ON UNIT NO. 12.

Test No.	Leeds and Northrup / Switch-board	Leeds and Northrup / Allis-Chalmers	Allis-Chalmers / Switch-board
200	1.016	1.001	1.014
201	1.021	1.001	1.020
202	1.026	1.000	1.026
203	1.019	1.003	1.019
204	1.023	1.002	1.021
205	1.030	1.004	1.026
206	1.023	1.002	1.021
207	1.028	1.002	1.026
208	1.030	0.999	1.031
209	1.027	1.004	1.026
210	1.030	1.003	1.026
211	1.021	0.989	1.033
212	1.025	0.991	1.034

A more satisfactory procedure will be to select those tests which appear to possess the elements of precision. If several of the tests plot on both the gate-discharge and gate-power curves, and are otherwise consistent, they may well be given the greater weight in drawing the final efficiency curve, which, owing to the paucity of tests over a large range of gate openings for this unit, may be extended parallel to the efficiency curve of Unit No. 13, which has been drawn on the diagram as a broken line.

Tests 207 and 212 plot well in this respect, as do 200, 205, and 208. Several others, 202 and 210, for example, are not seriously off, in this regard, though a combination of discrepancies throws the former downward.

It is not difficult to account for a slight deficit in the performance of Unit No. 12 as compared with Unit No. 13. The hydraulic conditions were plainly not so good for the former. Indeed, the turbulence in the head-races of the units increases in violence as the west end of

the power-house is approached, No. 11 being in a less favorable location than No. 12. There is also a possibility that No. 12 was not so well adjusted as No. 13, very small differences in this respect having an appreciable effect on the net performance of the unit. This, however, was contrary to the expectations of the makers, who claimed that Unit No. 12 was in better condition than Unit No. 13.

The probability of a constant error as large as 0.75% in the tests of No. 12 is very small, as has been amply shown by a full discussion of the errors of the chemical method in Part II. There may be a possibility of 0.1 or 0.2% error of this class, but, without further evidence, there is no justification for such an assumption.

Plate L, Unit No. 11.—The plotting of the first series of tests, 105-109, on this unit is shown by circles on Plate L. The discharge measurements are fairly consistent, but the power is not. Test 105 is wholly untrustworthy as to power, as the governor was free and the power absorbed by the water rheostat, which was improperly connected and hung in the tail-race, was affected by variations in water level and variations of salt concentration. Consequently, the gate varied throughout a large range, thus throwing considerable doubt on this particular test. All the other tests were made on the regular load, and an attempt was made to keep the power factor in the vicinity of 85. Table 62 gives the power factor as computed and also as read from the power-factor indicator.

TABLE 62.—Power Factor Observations in Tests on Unit No. 11. Second Series.

Test No.	Power factor computed.	Power factor indicated.
111	.....	.....
112	0.855	.....
113	0.814	.....
114	0.885	.....
115	0.851	0.845
116	0.883	0.868
117	0.862	0.950
118	0.843	0.857
119	0.867	0.920
120	0.865	0.950
121	0.852	0.860
122	0.864	0.860
Mean	0.849	0.889
Mean, excluding 112	0.853	

The average power factor, therefore, was almost exactly 0.85, which was the contract requirement.

All the tests of the second series have a very consistent relation to the Holyoke tests on the model runner when stepped up to the full size, as on Plate LI, with the exception of Test 122, which cannot be considered as trustworthy on account of the errors introduced into the tail-race samples by reason of a change to sample bottles which were not thoroughly cleaned, as mentioned in Section 109. Where there are divergencies from a satisfactory plotting on Plate L, there are also properly related divergencies of speed from the contract requirement of 100 rev. per min. On the whole, the second series of tests on Unit No. 11 approximates in precision the third series on Unit No. 13, with only such errors as may be expected with the less reliable power readings and the greater haste in making the tests on the former. The chemical work is not quite as satisfactory as on Unit No. 13, but shows no serious evidence of rough work.

The fact that the efficiency does not show as high, relatively, as that of the direct-current machines is probably due to the fact (mentioned in connection with the tests on Unit No. 12) that the hydraulic conditions grow steadily worse as this end of the power-house is approached from the east, where Units Nos. 13, 14, and 15 are situated. On the whole, there is no evidence that there is any serious constant error in respect to the finally determined efficiency curve for Unit No. 11.

111.—Diagram of Turbine Performance.—It is only very recently that systematic attempts have been made to secure greater efficiency of power-house operation. This is in line with suggestions made in reports by the writer in 1910 and subsequently. As a general rule, each power development will require individual investigation to secure a complete answer to this question. There is one feature of it, however, which can be treated generally, and that is the characteristics of the hydro-electric units in the power-house. The performance of these units is subject to exact analysis, and diagrams of performance can be constructed which will facilitate an intelligent and effective oversight of this operation.

Most of the diagrams which have been constructed for the analysis of turbine performance have been made by designers and builders, and such diagrams, as a rule, are not adapted to the uses of power-house

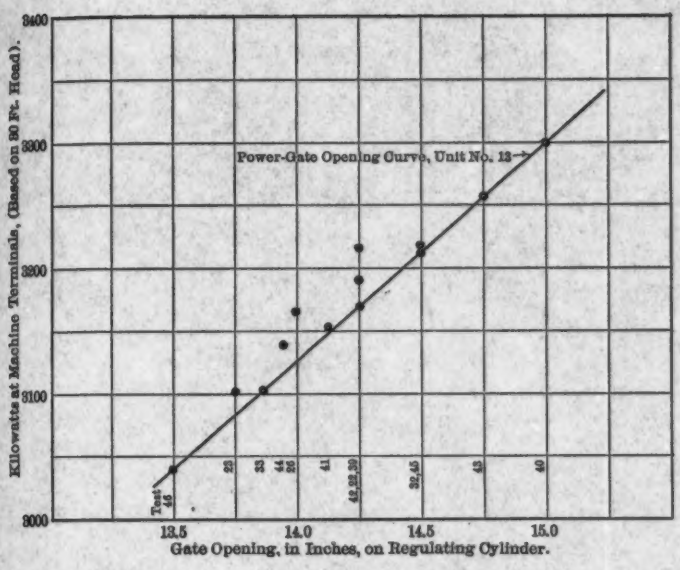
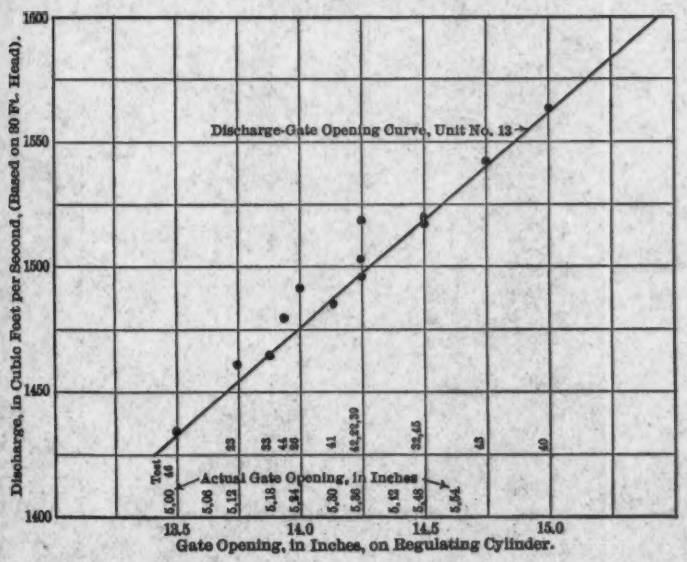
TESTS OF UNIT NO. 13.
TESTS 22-46. THIRD SERIES.
AUGUST 21ST TO SEPTEMBER 2D, 1914.

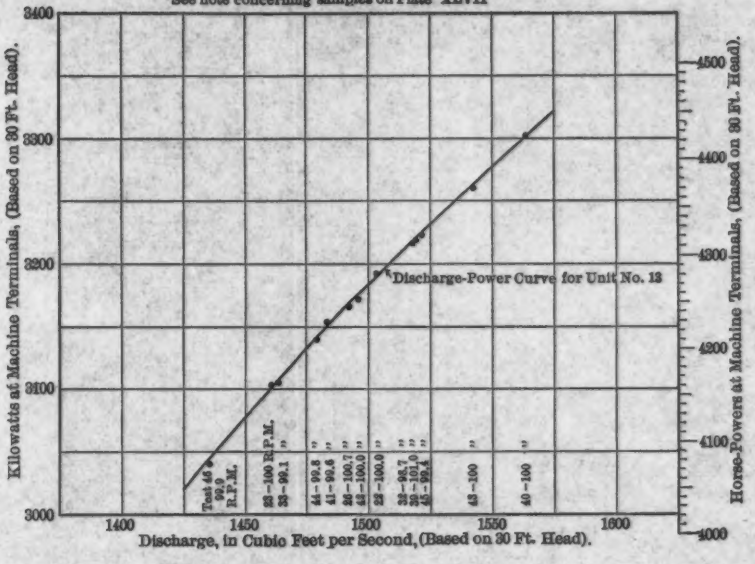
Tests 24, 25, 27-31, and 34-38 represent current-meter tests and are not shown on this plate. Dosed Tail Sampling Pipes on Upper Section, Tests 26-46. Dosed Tail Sampling Pipes on Lower Section, Tests 22-23. Tests 22 and 23 had 8 Sampling Pipes on Upper Section also. The speed in this series of tests is so near to 100 Rev. per Min. that no correction in plotting has been made, except in Tests 32 and 39. C—Plotting corrected to 100 Rev. per Min. by Plate LI. Gate openings being uncertain, the gate-opening power and gate-opening discharge curves are not well located.

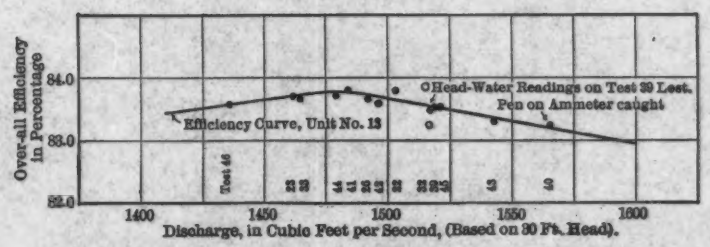
Generator efficiencies unknown. Test 19, Plate XLVII might be added to this series with propriety.

See note concerning samples on Plate XLVII









superintendents and overseers. Therefore, it is very desirable to have diagrams constructed especially for such purposes, and the following method has been used successfully by the writer for a number of years.

Relative to the performance of hydraulic turbines, theory and experience prove the following theorems, which, for brevity, are stated in the form of equations:

$$\text{At any fixed gate opening....} \left\{ \begin{array}{l} N = n\, h^{\frac{1}{2}} \\ P = p\, h^{\frac{3}{2}} \\ Q = q\, h^{\frac{1}{2}} \end{array} \right\} \text{.....(196)}$$

In which, N = number of revolutions per minute;

P = number of horse-powers developed by the runners;

Q = discharge, in cubic feet per second;

h = the head acting upon the wheels, in feet;

and n, p, q = obvious coefficients of performance.

These coefficients have been defined by some writers as being, respectively, the speed, power, and discharge of the turbine when operating on 1 ft. head. That is, the corresponding values of N, P, and Q when $h = 1$ are the values of n, p, and q. This is somewhat misleading, because, under this extreme condition, it might be impossible to get the turbine to operate. At least, it is not likely that such a definition should be taken literally. Coefficient of performance is a better term.

Again, both theory and experience show that p and q depend on the value of n, so that, in addition to Equations (196), we have

$$\text{At any fixed gate opening....} \left\{ \begin{array}{l} p = f_1(n) \\ q = f_2(n) \end{array} \right\} \text{.....(197)}$$

which symbolize the fact that both p and q are determined as soon as the value of n becomes fixed. Therefore, when n is fixed, both P and Q are definitely connected with h. In words, the theorem may be expressed as follows:

When the gate opening of the turbine and relative peripheral speed of the runner are held constant, that is, when the speed is adjusted to the head, the power of a turbine varies as the square root of the cube of the head, and the discharge varies as the square root of the head.

It is seldom, however, that the gate of a turbine can be set accurately by the ordinary gate mechanism, and, conversely, it is seldom that

the opening can be determined from the reading of a register operated by the mechanism. In any case, it is not necessary to successful power-house operation to know at all times what the gate opening may happen to be. The object may be accomplished in another way. Instead of using gate opening, the discharge or power of the turbines, and therefore of the power-plant, much more important quantities for the power-house superintendent to know may be made use of with equal facility.

Thus the relations expressed in Equations (197), though they may not be stated in the form of equations, are, nevertheless, equivalent to two equations between the four quantities, n, p, q, and gate opening. Consequently, a single relation may be derived from them connecting only the three quantities, n, p, and q, the fourth having been eliminated. Therefore, it may be formally stated that:

Each of the three quantities, n, p, and q, are dependent on the values of the other two only, the relation being expressible in the form of an isogram.

In particular, p may be expressed as a curved scale (series of curves) drawn to the rectangular co-ordinates given by n as abscissas and q as ordinates without reference to gate opening.

Now, the efficiency of a turbine may be written

$$\phi = \frac{550}{\gamma} \frac{P}{Q\,h} \qquad \text{.....(198)}$$

from which, by substituting values from Equations (196), we have

$$\phi = \frac{550}{\gamma} \frac{p}{q} \qquad \text{.....(199)}$$

γ being the specific weight of water.

Therefore, ϕ, like p, may be represented isogrammatically with reference to the same system of co-ordinates, n and q.

It follows from these relations that a diagram can be constructed connecting the speed, head, and speed coefficient, n, according to the relation indicated by the first of Equations (196), resulting in an isogram giving the values of n in the form of a curved scale, where values of h and N are plotted as rectangular co-ordinates. Better still, the curved scale for the speed coefficient becomes a system of radiating straight lines if the square roots of h are taken as the ordinates, or abscissas, as convenience may suggest.

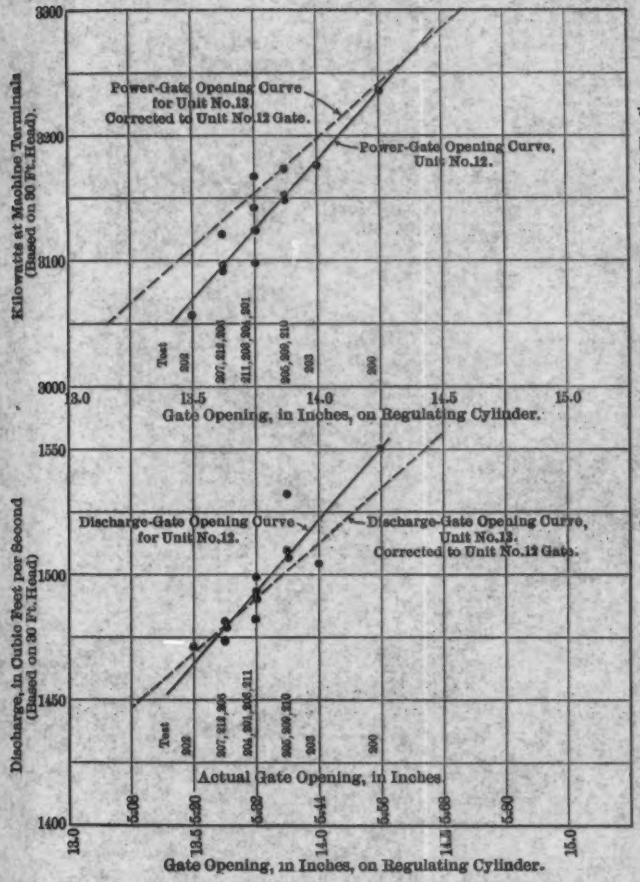
FINAL CURVES,
TESTS OF UNIT NO.12.
SEPTEMBER 28TH TO OCTOBER 13TH, 1914.

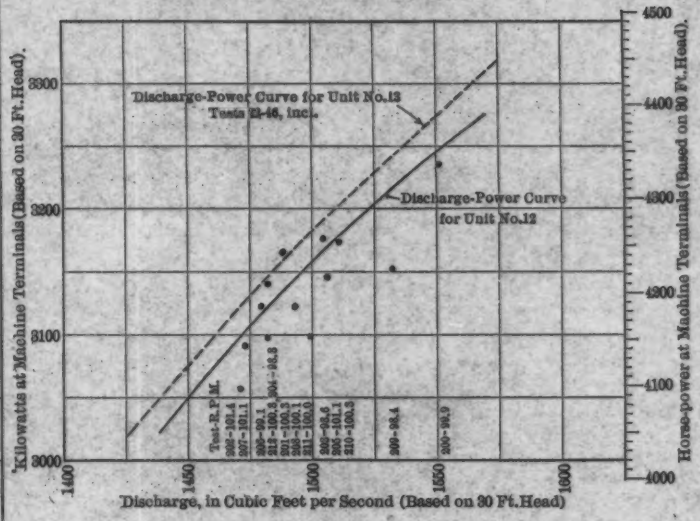
c=Plotting from tests corrected to 100 Rev. per Min. by Plate LI.

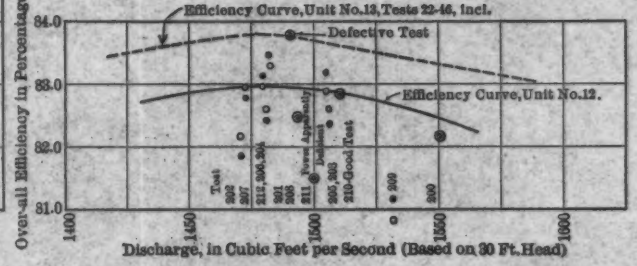
● Plotting from tests which do not change by Plate LI

Note: Correction of plottings by Plate LI uncertain to a small extent, as generator efficiencies are not known exactly.

Gate openings being uncertain, the gate-opening power and gate-opening discharge curves are not well located.







Hence this isogram for n, N, and h, when plotted to the square roots of h, provides a scale of straight lines representing n, and this scale may be taken as the abscissas of a system of co-ordinates in which an arbitrarily chosen scale for q represents the ordinates.

This latter system may then be used in constructing scales for ϕ and p, referred to n and q.

Finally, the original scale for head, h, may be used in conjunction with the scale for power coefficient, p, to form a system of co-ordinates (non-rectangular) for plotting the power of the turbine, P. In similar manner, the head scale and scale for discharge coefficient, q, determine a system of co-ordinates for plotting the discharge, Q, of the turbine.

Plate LI illustrates this method of plotting turbine performance. It gives the performance of one of the 80-in. twin-runner hydraulic turbine units which were tested, based on the results of Test No. 2 218 at Holyoke.

The speed and head scales and the sloping scale of relative speeds all appear as straight-line scales. These three scales and the corresponding quantities are connected by the first of Equations (196), the head scale being plotted to the square root of h and the speed scale being graduated according to the relative peripheral speed of the runner, rather than to n itself. This relation is given by the equation:

$$\text{Relative peripheral speed} = \frac{\pi}{60\sqrt{2g}} \frac{d\,N}{h^{\frac{1}{2}}} \qquad (200)$$

where d is the diameter (frequently only nominal) of the runner. If s is the relative peripheral speed, the relation expressed in Equation (200) may be written

$$s = 0.00653\, d\, n \qquad (201)$$

which is the equation used in the construction of the sloping scale of the diagram.

Having constructed the scale of relative speeds, or relative peripheral speeds, according to convenience, an arbitrarily chosen scale may be constructed for the discharge coefficient, q. The writer prefers to draw this scale to the left of the lowest number of revolutions per minute likely to be of frequent use. The scale may be composed of vertical parallel lines, conveniently spaced with regard to any desired degree of precision. The graduations for this scale appear along the upper margin of the diagram.

After constructing the discharge coefficient scale, which would be clearer if in a distinctive color, say green, the power coefficient may be plotted, say in carmine, with reference to n, or s, and q, according to the relations in Equations (196). Thus, from the records of the test,

$$\left.\begin{aligned} n &= \frac{N}{h^{\frac{1}{2}}} \\ p &= \frac{P}{h^{\frac{3}{2}}} \\ q &= \frac{Q}{h^{\frac{1}{2}}} \end{aligned}\right\} \quad \text{(See Equations (196))} \ldots\ldots\ldots (202)$$

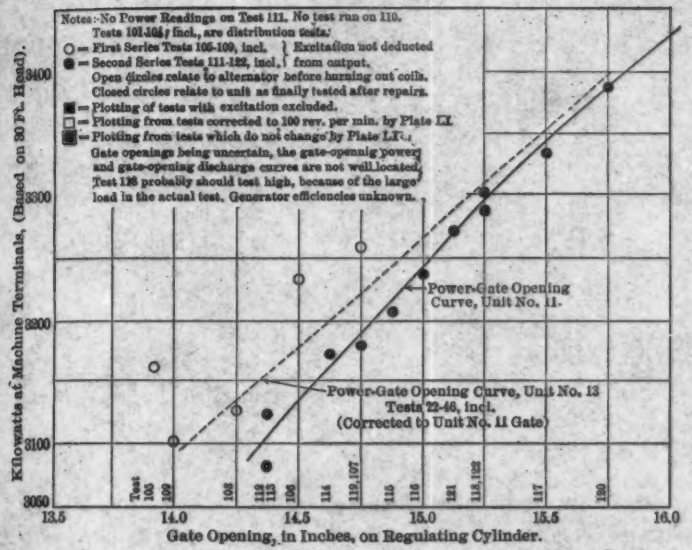
which furnishes the data for plotting p to the co-ordinates, n and q. If it is desired to plot to s and q, then Equations 200, or 201, must be used.

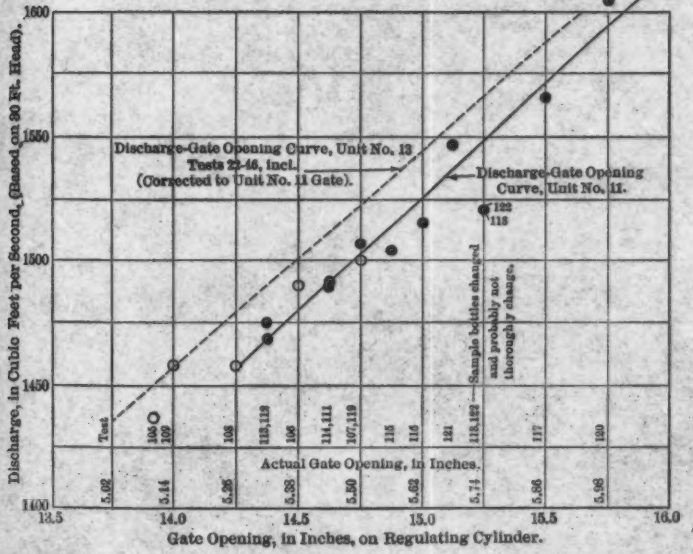
Turning attention now to the co-ordinate scales for p and q, it is seen that each intersects the original scale of heads, produced if necessary. Hence, by the second and third of Equations (196), scales for P and Q may be constructed, as shown on the left half of Plate LI. To be in keeping with p and q, the scales for P and Q should be in the same colors as their corresponding coefficients, p and q. Hence, in this case, the scale for Q may be green and that for P may be carmine.

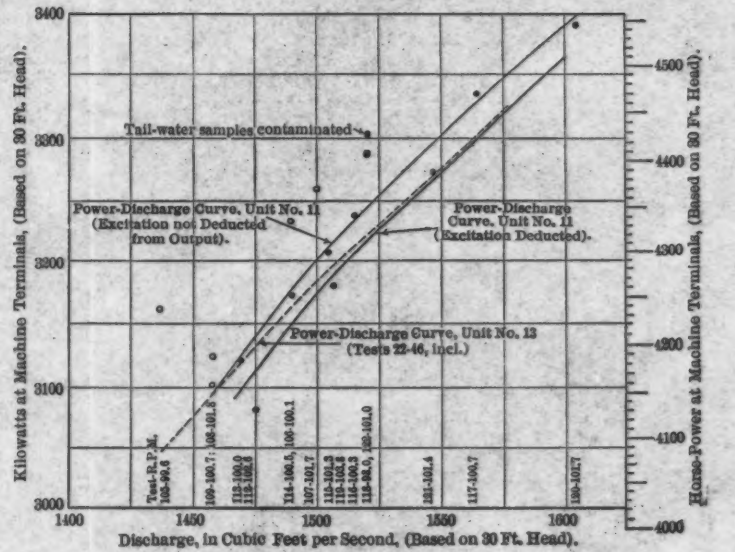
Finally, the efficiency curves may be plotted from the relations of Equations (198) or (199). These curves may be made more distinctive by being plotted in white on a dark background. If desired, curves of gate openings may be plotted in broken, or dotted lines, across the face of the diagram, thus making a complete picture of the operation of the turbine unit in its relation to the actual conditions of head, speed, power, discharge, efficiency, and gate opening.

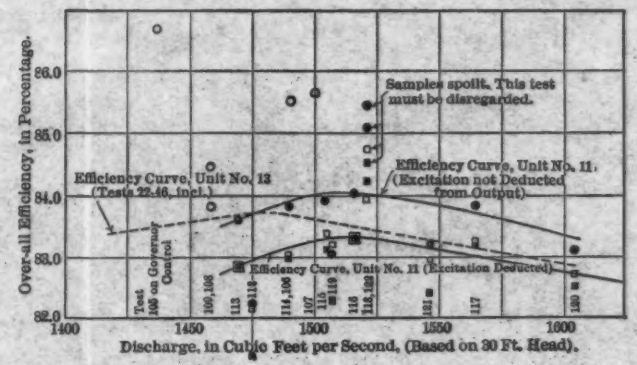
112.—Use of the Turbine Diagram.—Although the plotting of such a diagram involves considerable labor, its use is very simple, and the information it furnishes is extremely valuable in the supervision of power-house operation. The superintendent is able, in a few moments, by examining the diagram, to tell whether a particular unit is operating under favorable conditions or otherwise. He can tell whether a unit is developing all the power it should, under the conditions. If the trash racks become choked, the loss of head makes itself felt by cutting down the output of the unit, and this is instantly shown by

FINAL CURVES.
TESTS OF UNIT NO. 11.
SEPTEMBER 12TH-SEPTEMBER 18TH 1914.
NOVEMBER 9TH-NOVEMBER 21TH 1914.









reference to the diagram with the actual power output, speed, and difference in elevation of head- and tail-water. An inspection of the racks is not nearly so effective as this comparison of the actual and diagrammatic outputs. The racks may be clear but the runners may be choked, perhaps not sufficiently to attract the attention of the operators by a large reduction of power, but the deficit will be clearly shown by the diagram. The superintendent can check the methods of the individual operators by examining the performance of the units at various times.

113.—To Find the Efficiency, Discharge, Relative Speed, and Gate Opening of the Unit, with Given Power, Speed, and Head.—Suppose the head is 30 ft., the speed is 100 rev. per min., and the power is 4 700 h.p. Enter the diagram on the right at 100 rev. per min. on 30 ft. head. The point thus located determines the relative peripheral speed to be about 79½%, which can be read at the extreme left of the diagram near the bottom. It is not necessary to make this reading unless desired. Fix the point just located on the diagram by making a dot, or conveniently with a thumb-tack, or pen-point laid on the diagram. Locate and fix another point at the intersection of 30 ft. head with the curved scale of power at 4 700 h.p. The intersection of the relative speed line through the first fixed point (interpolated by mental estimation when necessary) with the power coefficient line through the second fixed point (also interpolated in this case) locates a third point on the diagram, which, in this case, lies within the closed curve of highest efficiency, 90 per cent. This point should also be fixed on the diagram.

Vertically, above this last point, that is, parallel to the discharge coefficient lines, at the given head, 30 ft. in this case, locate a fourth point which determines the discharge, $Q = 1\,520$ cu. ft. per sec., as shown by the discharge scale.

The gate opening, according to the Holyoke test, can be determined from the gate-opening curves, dotted on the diagram, by making the reading at the third point located on the diagram, at the intersection of the relative speed and power coefficient lines, in this case within the closed curve of 90% efficiency, as has been explained. This is about 72% of full gate, according to the plotting. Gate openings are of little use for purposes of this kind, but discharges are very important. Hence it is preferable to have the discharge coefficients

plotted as parallel vertical lines, rather than the gate openings, as it is necessary to project the locations of points in the direction of the discharge coefficient lines very frequently, and these projections can be most easily and correctly made with reference to parallel straight lines.

In the supervision of power-house operation, it is recommended that frequent, daily, or even hourly, reports of the operating conditions be made. These reports should give the output of each unit, with its maximum possible output under the conditions. The actual total output of the power plant, with its maximum possible output under the conditions, should also appear. Where these actual and maximum possible outputs show unreasonable discrepancies, an investigation should be started at once to ascertain the cause.

114.—Proper Speed and Load for Turbines.—In the case of alternating-current machinery, the units are usually restricted to a certain definite speed. In this case the greatest of care should be exercised in selecting turbines which will drive the generators at that speed, simultaneously operating at their maximum efficiency and best rated load. If the intending purchaser will have the makers guarantee performance according to a diagrammatic plotting such as outlined, perhaps limiting the guaranty to a certain operating area, or areas, of the diagram, he can then assure himself in advance of the efficiency which he can obtain at his proposed plant. A contract which simply requires a certain maximum efficiency may fall far short of securing the desired results, for the reason that conditions may seldom admit of operation at that particular efficiency. The important relation of speed to power may be drawn off such a diagram very simply by first observing what relative speed line, or lines, pass through the most desirable field of conditions on the diagram. If the turbine can operate at its best load most of the time, the more restricted, smaller field of higher efficiencies can be made available; but, if the load must vary over a considerable range, it may be found that the higher efficiencies would seldom or never be available.

As an example of the relations between speed and load, Table 63 has been compiled from Plate LI, from which it appears that the turbine unit can develop 90% efficiency only between heads of 27.5 and 32.2 ft., if the speed must be held at 100 rev. per min. The best head is 30 ft., giving the widest range of power.

PLATE LI.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXX, No. 1366.
GROAT ON
CHEMI-HYDROMETRY.

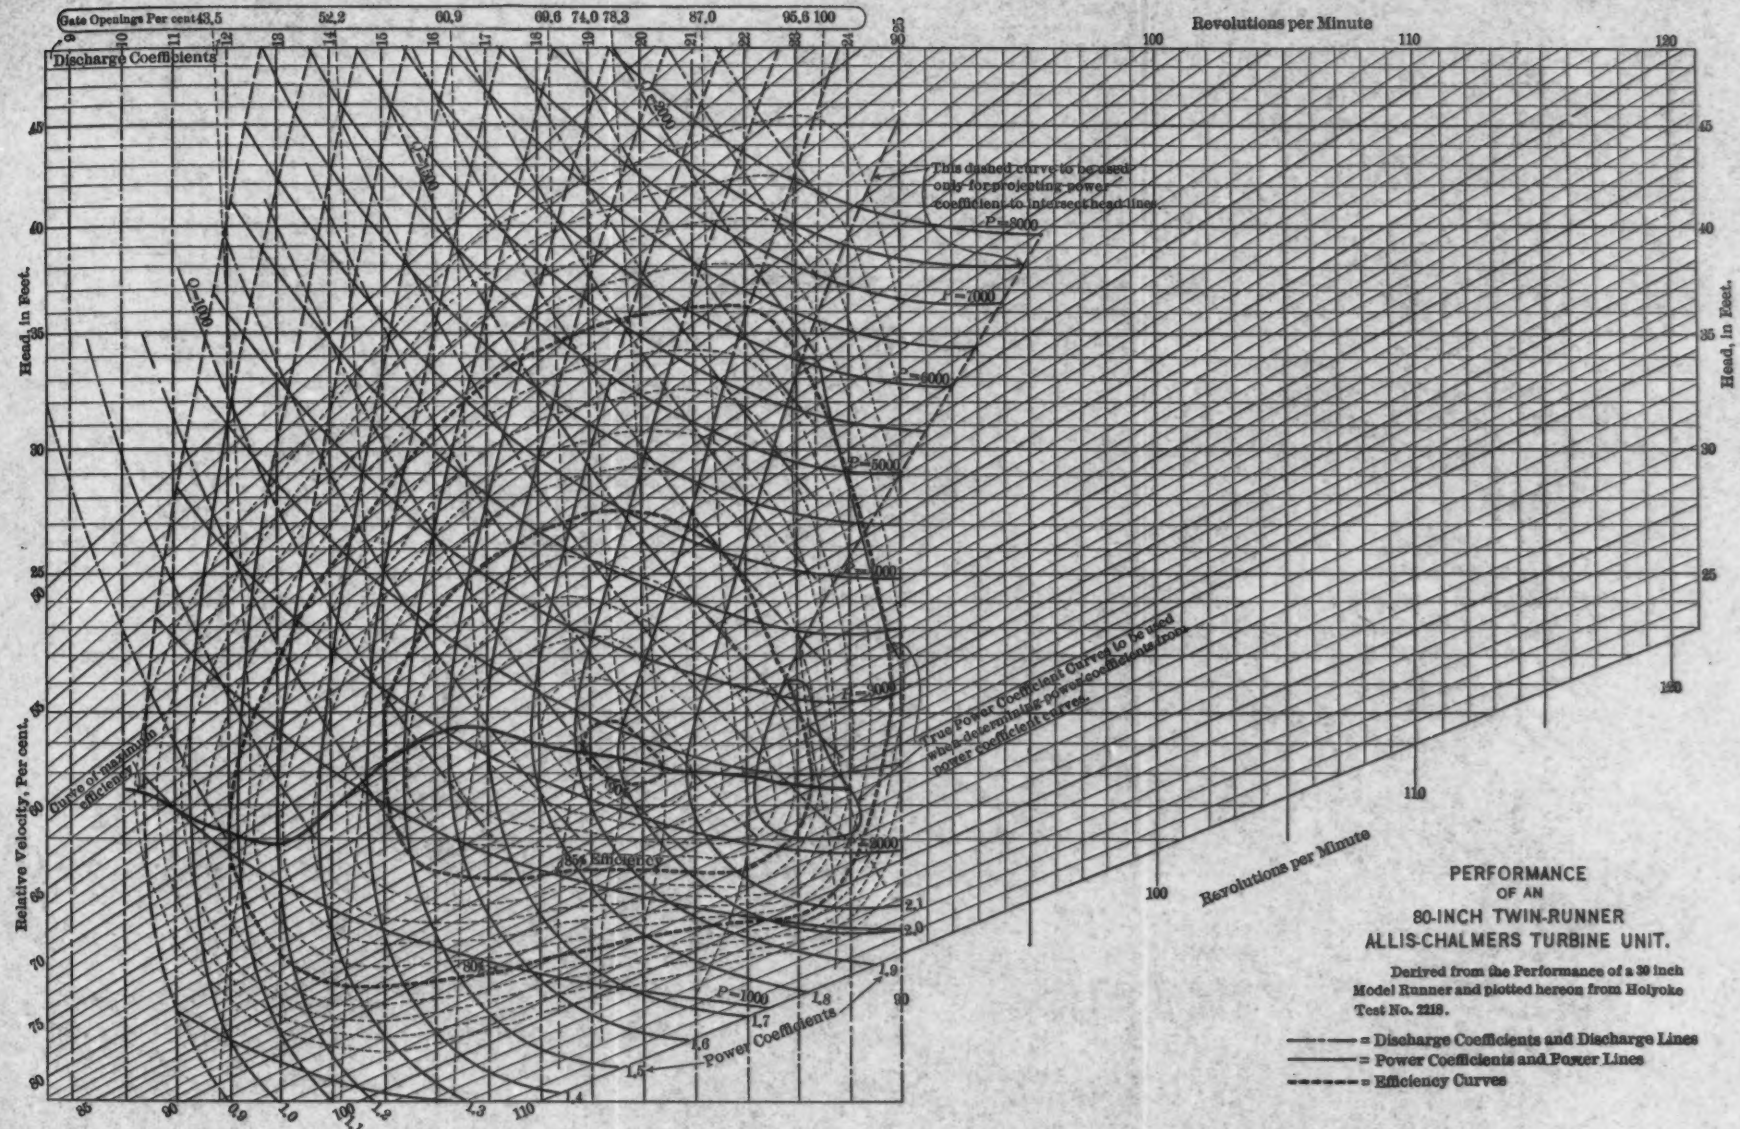


TABLE 63.—RANGE OF POWER AT VARIOUS HEADS DEVELOPABLE BY ONE TURBINE UNIT AT 100 REV. PER MIN. AND 90% EFFICIENCY, AS SHOWN BY PLATE LI.

32.0	5 100	5 200	100
32.2	5 200 +	5 200 +	0

Again, when wider ranges of power are required with this unit, it must be at the expense of efficiency. Suppose it is desired to ascertain the range of power at 88% efficiency. Such an investigation appears in Table 64, which shows that a small sacrifice in efficiency secures a very much wider range of operating conditions, which will be found very necessary in many cases. Contracts, therefore, should have due regard to such requirements of operating conditions, and diagrams similar to Plate LI will govern the specifications for turbine performance.

TABLE 64.—RANGE OF POWER FOR ONE UNIT AT 100 REV. PER MIN. AND 88% EFFICIENCY, AS SHOWN BY PLATE LI.

38.0	5 800	6 300	500
39.0	6 200	6 200	0

*Somewhat doubtful.

In cases where the speed of the units may be varied within certain limits, as with direct-current generators, or isolated alternating machines, it may be desirable to adjust the speed to the head and power, so as to secure maximum efficiency. Table 65 is a study of this kind compiled from Plate LI.

TABLE 65.—ADJUSTING THE SPEED TO HEAD AND POWER WHEN FEASIBLE.

* Doubtful if this could be fully realized.

In compiling a table of this kind, a line of maximum efficiencies for given power coefficients drawn on the diagram facilitates the compilation greatly. Thus, from the intersection of the given power and head, project the interpolated power-coefficient line by mental estimation until it intersects the curve of maximum efficiency. Enter in the table the efficiency reading from the efficiency scale. From the intersection last located and fixed, project the relative speed line by mental estimation until it intersects the given head line. Enter in the table the revolutions per minute, read from the speed scale, and proceed similarly with the next given head and power.

A similar table, taking into account generator losses and efficiencies, and thus relating to the performance of an entire unit, may be placed in the hands of the operator, with instructions to adjust the speed to the head and power according to the indications of the table.

Of course, a diagram based on the principles used in constructing the curves of Plate LI may be made, but taking into account, in addition, the performance characteristics of the generator, thus resulting in direct relations between the electrical output of the unit and the other quantities involved in Plate LI. For many purposes, such a diagram will prove to be of great value.

115.—Relations of Tests in Place to Holyoke Tests.—It is intended to make diagrams similar to Plate LI for the performance of the entire units, basing the data on the results of the tests, and taking into account, as fully as possible, the performance of the generators along with the turbines. Such a study will consume more time and space than the scope of the present paper will admit. Table 66, however, gives an approximate comparison of Holyoke tests with place tests based on assumed generator efficiencies. Owing to the uncertainty as to generator performance, no tests having been made on them, the comparison is only of passing interest.

It will be observed that there are relatively large efficiency corrections for Tests 32 and 39, Unit No. 13, due to relatively large deviations of the speed from 100 rev. per min. during the tests. It is doubtful if the speed was so much in error during these tests. Hence the corresponding discrepancies on Plate XLVIII of the corrected plottings of these tests, indicated by open circles, are, very likely, excessive.

Attention is called to this, as the fact suggests the desirability of having a complete count of the total number of revolutions during each test, along with frequent speed determinations for shorter intervals. Had this been done, it would be possible to locate the cause of the discrepancies in the two plottings.

PART V.

CURRENT METERS.

SUMMARY.

116.—Current meters were run in parallel with the chemical equipment in a number of the earlier turbine tests as a precaution. These are marked: *D, E, G, H, I, K, L, N, O, S, T, U,* and *V.* Tests which were made with meters only are marked: *B, C, F, J, P, Q, R,* 1, 2, 3, 4, 5, 27, 28, 29, 30, 31, 34, 35, 36, 37, and 38. More than 4 000 individual velocity observations were made with the five current meters.

Ratings were made for these meters at the Naval Tank of the University of Michigan with the efficient equipment and expert advice of Professor H. C. Sadler. These ratings were made in still water, with and without oscillations. Oscillations of three kinds were caused: longitudinal, vertical transverse, and horizontal transverse, of various degrees of amplitude and period. Figs. 32, 34, and 36 are examples.

The particular meters rated were: Haskell No. 1, Haskell No. 2, Ott No. 2311, Ott No. 2312, and Price No. 1553.

The following propositions, which are restatements of those previously made by the writer* are verified, with some modifications in the case of the small Price meter, under certain circumstances.

When a cup meter is run in turbulent water it will register a larger number of revolutions per second than a perfect still-water rating would indicate.

When a screw meter is run in turbulent water it will register a smaller number of revolutions per second than a perfect still-water rating would indicate.

If both types of meter are used simultaneously in turbulent water, the disparity between the discrepant velocities thus determined by the still-water rating may be taken as a basis for correcting the discrepant velocities.

In these ratings, the tails, or rudders, of the meters were removed, and the meters were rigidly attached to oscillating arms capable of motions in the three directions mentioned. Three meters were thus rated simultaneously, the three arms oscillating in unison and the meters pointing in the direction of motion of the car.

---

* *Transactions*, Am. Soc. C. E., Vol. LXXVI, p. 819.

This method of holding the meters rigidly in one direction is very unfavorable to the screw meter and favorable to the cup meter, the result being that the screws are retarded in most cases by a larger amount, and the cups are accelerated by a smaller amount, than would be the case were the meters free to swing.

It appears to be the case that, for velocities greater than 1.5 ft. per sec., the relative errors of all types of meters are nearly, if not quite, constant for the same relative amount of oscillation or turbulence. This further appears to be nearly realized for velocities of less than 1.5 ft. per sec. Thus, in the case of Ott meter No. 2311, Fig. 34, the retardation is uniformly 5 to 6% for transverse oscillations averaging about 30% of the velocity of the rating car, with amplitudes of 2 or 3 ft.

In the head-races during the turbine tests two Haskell meters, two Ott meters, and one Price meter were attached to a rack, composed of angle irons, Fig. 25, Section 97, in exactly the same manner as they were attached to the rating car, the eddying motion of the water, however, taking the place of oscillations.

It was shown by Tests 24, 25, 70, 71, 72, and 73 that this rack had a retarding influence on the meters of a greater or less degree. It is clear that the rack would cut off the water flow in the obstructed part of the section, crowding it into the rest of the raceway. Thus a meter in front of the rack would record lower velocity and one in the unobstructed part of the section higher velocity than with the rack removed.

In the vertical transverse oscillating tests of the small Price meter, there are certain relative amounts of oscillation which have the effect of retarding the meter rather than accelerating it. Above and below this relative amount, acceleration results. To this extent the cups are retarded rather than accelerated, but, on the average, as in the usual gauging section, and as in the case of the present tests, it appears that the net effect on the meter was acceleration.

Longitudinal oscillations have very little effect on the still-water ratings of the meters. For this reason the longitudinal oscillations are neglected in the discharge computations.

117.—Current-Meter Tests.—It would not be rational to conclude this paper without making a comparison of the results by the chemical

method with those by current meters. It is of very great interest to learn how closely the two methods consist with each other. This comparison has a double value. It confirms the theories advanced for chemi-hydrometry and simultaneously shows how accurate current-meter work can be, under the very unfavorable conditions of flow in a head-race where no precautions have been taken for "stilling" the water for the purpose of gauging the discharge.

Although the two methods check each other well within 1%, it would scarcely be wise to assert that current meters, under these adverse conditions, will always yield results correct to a fraction of 1 per cent. It is clear, however, that, if meters of properly related types are used in conjunction with an intelligent statistical study of their performance, results of a remarkably high degree of precision can be obtained, even under very unfavorable hydraulic conditions.

No attempt will be made to effect a complete digest of all the current-meter observations. The object will not be to make the best possible use of the current-meter data, but rather to arrive at a hasty estimate of the discharge for each test where the current meters and chemicals were used in parallel, thus leading to an immediate comparison of the two methods.

118.—Assumptions.—It is always necessary to make assumptions when computing rates of discharge based on the records of current-meter observations. The usual method requires the assumption that the meters perform the same in turbulent water as in still water. This assumption is entirely too narrow for precise work, and has not only been controverted on many occasions by eminent engineers, but has been proved beyond question to leave the resulting estimates in doubt by a large margin.

The results will be the more reliable the more nearly the assumptions are in accord with the facts. In this series of tests, therefore, it is assumed that both horizontal transverse and vertical transverse oscillations of the meters in the ratings represent horizontal and vertical disturbances in the meter section during the actual discharge observations. The effects of longitudinal oscillations have been shown in the ratings to be very small. It is assumed as a consequence that the effects of longitudinal perturbations, or pulsations, in the meter section are also very small. Such effects, accordingly, are neglected.

The ratings at Ann Arbor show conclusively that, for the method of holding the meters, the small Price meter will, on the average, be accelerated, and the Haskell and Ott meters will be retarded, and that the Haskell meter will be retarded by a larger amount relatively than the Ott meter. These differences in the characteristics of these three types make determinate the problem of estimating the discharge with a considerable degree of precision. Two meters which perform exactly alike, thereby giving perfectly consistent results, however, are worthless for the purpose of measuring velocities in turbulent water with precision.

The fact, stated by W. G. Price, M. Am. Soc. C. E., in his discussion of the writer's former paper, that vertical disturbances (when the meter axis is vertical) tend to counteract the effects of horizontal components of motion, does not assist in determining true velocities by using two or more different types of meter, but, on the contrary, rather hinders the determination. This hindrance arises from the necessity of making diagrams for the purpose of separating the two classes of disturbances and, indeed, of determining, so to speak, the relative amounts of horizontal and vertical disturbance.

In this respect it would facilitate matters considerably to have meters each of which suffers equal deviations for equal degrees of either of these two classes of turbulence. The Haskell and Ott meters are of this kind, but both are retarded, whereas, for the most accurate work, the deviations should be in opposite directions. In the present case we must rely principally on the true velocities as determined by the two combinations, Haskell-Price and Ott-Price, though the combination, Haskell-Ott, must not be disregarded.

It may be repeated here that, by properly designing a runner of the screw type with the vanes slightly cupped in the right sense, it should be possible to construct a current meter giving records practically correct in all usual cases of turbulent flow. Mr. F. Nagler has made such an instrument, though his experimental study is not yet completed. The last runner produced gives records which are more nearly correct than those of any meter with which the writer is conversant.

119.—The Statistical Method.—The term "statistical" as here used relates to the values of averages as deduced from aggregates rather than from the study of each individual element in detail. The usual

method in discharge gauging is to find a number representing the velocity at a particular point in the meter section, and to take the product of this velocity and the area associated with the point as representative of the discharge through this area. The sum of all such products is the discharge for the entire cross-section. In the statistical method, the aggregate, or sum, of all the velocities in the meter section may be multiplied by the distribution factor* to determine at once the mean velocity in the section. The area of the section, as a function of the elevation of the water surface, taken from a table, or curve, may then be multiplied by the mean velocity to determine the total discharge, thus saving a large amount of detail.

The distribution factor is the ratio of the mean velocity in the section to the sum of the metered velocities at a fixed set of points in the cross-section. If V_m is the mean velocity in the section (unknown), A the aggregate meter velocity, that is, simply the sum of the metered velocities, N the number of meter points, and v_m the arithmetical mean of the meter velocities, the distribution factor is:

$$\text{Distribution factor} = \frac{V_m}{A} = \frac{V_m}{N\,v_m} \quad \ldots\ldots\ldots\ldots (203)$$

Now, N is known, and the ratio, $V_m \div v_m$, is confined within very narrow limits for a large variety of cases if the meter points are distributed uniformly, or nearly uniformly, over the area. When the meter points are spaced uniformly across the usual river, the ratio is decreased to a somewhat larger extent, but even then it is pretty well confined to values between 0.92 and 0.96 for such sections as are chosen for gauging stations. For a liberal number of points distributed uniformly over the area of a large raceway, even when the conditions of flow are unfavorable, the ratio usually lies between 0.98 and 0.99, 0.985 being a close average. The tendency is for this value to increase with the size of the section. There may be cases, even in small sections, where it would be larger than unity. If the meters can be placed at points which determine the mean velocities throughout equal portions of the cross-section, the ratio of mean velocity to mean metered velocity becomes equal to unity, and the distribution factor is then simply the reciprocal of the number of velocities, that is, of meter points.

* Defined in the paper on current meters previously referred to. *Transactions*, Am. Soc. C. E., Vol. LXXVI, p. 837.

The value of the ratio $V_m \div v_m$, during the tests of 1911, was found, by a careful Pitot tube survey, to be 0.981 for the tail-races of the turbines.

120.—Subdivisions of Raceway.—The method of suspending and operating the current meters has been described fairly well in Part III. The equipment was arranged so that, by a simple adjustment, the meter points were placed at the centers of equal areas. The raceway was divided into 10 equal vertical and 10 equal horizontal strips, the 100 meter points being determined by the intersections of the 10 medians of the horizontal strips with the 10 medians of the vertical strips. A diagrammatic scheme is given herewith which represents the subdivisions of the raceway.

DIAGRAMMATIC SCHEME FOR METER POSITIONS.

	10										

The rack carrying the five current meters could be lowered until the meters were at the level of any set of meter points. By shifting the movable leaf of the rack until it was brought into contact with the west wall of the race, the five meters took their respective westerly positions for the set of meter points. After the velocities were determined at these points, the rack was shifted to its easterly position, and the remaining five velocities for this level of the rack were determined. The rack was then lowered to the next level.

In order to reduce the labor of computation, the five positions and five horizontals, respectively located by consecutive pairs of verticals and horizontals, will be used, instead of the individual meter points. Thus the square representing the area for the easterly and westerly situations of the rack for any position (Position 2, for example) in combination with any horizontal (Horizontal 3, for example) contains four meter points, and the sum of the corresponding velocities will be frequently treated in the sequel rather than the velocity at any one of the four points. This means a reduction in subdivisions from 100 to 25.

It will be observed that any one traverse of the raceway enables any one meter to determine the twenty velocities in the vertical which are determined by the position of the meter on the rack. This vertical, or position, may be treated as one of the five equal parts into which the race is divided, and the sum of the twenty corresponding velocities may be used as an aggregate, thus reducing the number of equal subdivisions to 5 instead of 25.

The necessity for these subdivisions is brought about by the fact that the meters do not give true velocities. Otherwise the aggregate for the entire cross-section would be immediately available for the determination of discharge.

121.—Current-Meter Records.—Tests G, H, I, K, L, N, O, P, Q, R, S, T, U, and V.—Instead of giving the current-meter records in full, a somewhat condensed form will be adopted for the purpose of simplifying the calculations. There were 100 velocity readings in each of the tests excepting those in which two traverses of the head-race were made by the meters, in which case 200 velocity readings were made. Test *O* is the only one of the latter description. In this test the average of the two readings at any one point is treated exactly as were the single readings in the other tests.

Two readings are given by any meter at each depth, one for the easterly and one for the westerly position of the rack. The race is divided into five equal strips, each containing two depths at which the meters were read. These strips will be called "horizontals". Thus, for any one position and any one horizontal, there are four velocity readings, and it is the sum of these four readings which appears in the following assemblage of data under any position and opposite any horizontal. Decimal points have been omitted, except in the means for

each meter and position, at the foot of each column. For example, the sum of the four velocities in Test *G* by Haskell meter No. 1, in Position 2, Horizontal 3, is 1 030, or 10.3 ft. per sec. The sum of all the velocities in Position 2 by this meter is 4 949, or 49.49 ft. per sec., and the mean velocity is 2.474 ft. per sec.

The writer is indebted to H. W. King, M. Am. Soc. C. E., for the use of a small Price meter and to Mr. W. M. White for the use of two Ott meters. These, with the two large Haskell instruments, were used in the Ann Arbor ratings, and in these tests.

Tables of Tests *G, H, I, K, L, N, O, P, Q, R, S, T, U* and *V*, are given showing the sums of the four meter velocities for each of the twenty-five equal rectangles formed by the lapping of the five vertical rectangles representing the meter positions, with the five horizontal rectangles representing the five pairs of consecutive depths at which the meters were operated.

The numbers in the tables are in units of $\frac{1}{1000}$ ft. per sec., decimal points having been omitted. The means are in feet per second.

TEST *G*.—JULY 22D, 1914.

122.—Rating Current Meters.—In order to secure accurate results by current meters in turbulent water, it is necessary to use more than one type of meter, in the absence of an instrument which will not deviate from its still-water rating. Accordingly, three types were used in the tests: two of the Ott, two of the large-sized Haskell, and one of the small Price type. The letters, H, P, and O, will indicate the

corresponding types, and subscripts, where necessary, will indicate the particular number of the instrument referred to, according to the following scheme:

H_1 = Haskell meter No. 1,
H_2 = Haskell meter No. 2,
O_1 = Ott meter No. 2111,
O_2 = Ott meter No. 2112,
P = Price meter No. 1553.

Three meters could be rated simultaneously, with or without oscillations. Each instrument was attached to an arm at the rear of the rating car, and all three arms were tied together in such a manner that any oscillation imparted to any one meter would cause all three to oscillate in unison over equal amplitudes and in the same direction. In this way the separate effects of equal oscillations on all three meters could be recorded.

Oscillations of various amplitudes and periods were tried, and in three directions: longitudinal, vertical, and horizontal transverse. The axes of the meters were parallel to the direction of the motion of the car in all cases, except that, in the longitudinal oscillations, the arms naturally gave the axes of the meters slight rocking motions in vertical planes parallel to the motion of the car. The effects of these longitudinal oscillations have been neglected, as they were not large.

As a general rule, the meters were retarded by longitudinal oscillations for such velocities as we now have to measure, so that no surprise will be warranted if the final estimates of discharge prove to be somewhat deficient, as compared with results by more accurate methods than have yet been devised for current meters.

Figs. 32, 33, 34, 35, and 36 give, each on one sheet, the complete series of ratings for one or other of the five meters. The method of constructing the curves, being simple, requires no explanation.

123.—Composite Rating Curves.—Plates LII, LIII, LIV, LV, and LVI, are diagrams for determining the true velocity at a point by two velocity readings taken at this point by two meters of different type.

The true velocity may be read from the curved scale by locating a point on the diagram opposite the velocity, or revolutions per second, by one meter, and over the velocity, or revolutions per second, by the other meter, based on still-water ratings, thus representing the co-ordinates of the point on the diagram. The construction of the

diagrams from the ratings on Figs. 32, 34, and 36, will be sufficiently clear to the reader in principle, though, for accurate work, subsidiary diagrams segregating the ratings of different classes were made.

The curves on these subsidiary diagrams, when the ratings are not very complete, are not consistently spaced in all cases, and some minor adjustments were necessary to make them more harmonious and probably more nearly correct than they would have been otherwise.

It was never intended by the writer to make use of two meters which are each retarded, or each accelerated, to determine velocities in

turbulent water. It was thought that, to secure the most accurate results, one meter should be accelerated and the other retarded. However, as the Haskell and Ott meters were both used in each test, a diagram of their composite rating, Plate LVI, has been prepared. This diagram possesses the seeming inconsistency that the higher of two readings by the Haskell meter for a given reading by the Ott meter corresponds to the lower of the two velocities indicated by the diagram, and *vice versa*.

On each of the five diagrams of composite ratings the solid lines correspond to the composite ratings of only one pair of meters, and the broken lines correspond to the average composite ratings for the two types of meter represented, as determined from the Ann Arbor ratings.

Plates LII and LIV are for horizontal transverse oscillations only, and Plates LIII and LV are made from curves drawn midway between those for equal degrees of horizontal and vertical oscillations. The latter two diagrams, consequently, assume equal degrees of horizontal and vertical turbulence, but omit longitudinal turbulence, as has been explained in Section 122. The former pair of drawings assumes only horizontal turbulence, omitting longitudinal and vertical perturbations. Plate LVI is for the Haskell-Ott combination. As these meters are practically constant in form for all planes through their axes, they should be equally affected by equal

degrees of any kind of transverse turbulence, horizontal or vertical. The tests show this to be the case. Hence only one diagram is necessary for this combination of meters. It is the change in rating of the small Price meter in passing from horizontal to vertical turbulence which necessitates the two diagrams when this instrument is involved, though it must be remarked, in justice to this meter, that it is, on the average, for the method of suspension and operation used on these tests, relatively nearer to its still-water rating than any of the others.

124.—Velocities in Tests G, H, I, K, and L, Based on Meter Corrections Deduced from Average Meter Velocities in the Five Positions in These Tests.—These five tests were intended to determine the meter corrections. They were made under very uniform conditions, and are nearly identical, except that the meters were shifted in a systematic manner from test to test, so that each instrument made the traverse of a different position in each succeeding test, thereby operating once at the intersection of any vertical position with any horizontal, that is, at 100 different points of the head-race, in the five tests.

Instead of comparing each pair of meters at each point in the head-race, thus necessitating a large amount of detail, the aggregate velocity for each test has been computed from the mean velocities given by the partial aggregates for the separate meters in each position.

Table 67 gives the average reading for each meter in each test for the 20 meter points in the position in which the particular meter was operated, reduced to the common discharge of 1 660 cu. ft. per sec., and to the common section area of 625 sq. ft. See Section 121 for the data from which the table is compiled.

Table 68 is a rearrangement of Table 67 for the purpose of assembling the records for each meter in each position, regardless of the particular test involved.

Table 69 determines the true average velocities for the five meters in the five positions, regardless of the particular test. In compiling this table, Plates LII, LIII, LIV, LV, and LVI, were used.

It is at once evident that the two velocities for any position determined for horizontal and vertical oscillations agree within about 1% of each other, as an average. The same may be said for the case of horizontal oscillations only.

TABLE 67.—EQUIVALENT MEAN INSTRUMENTAL VELOCITIES IN TESTS *G, H, I, K,* AND *L,* FOR A DISCHARGE OF 1 660 CU. FT. PER SEC. AND AN AREA OF 625 SQ. FT., BASED ON STILL-WATER RATINGS. UNIT NO. 13.

Position number.	Test.									
	G		*H*		*I*		*K*		*L*

Approx. discharge.	1 662		1 662		1 666		1 653		1 647	
Factor*.....	1.001		1.001		0.997		1.003		1.010	

* This factor was used to reduce the meter record tests *G, H, I, K,* and *L,* Section 121, to values corresponding to a discharge of 1 660 cu. ft. per sec. and an area of 625 sq. ft. The corrections are so small that they are frequently omitted.

It may be said, therefore, that the two velocities determined by the Haskell-Price and Ott-Price combinations agree fairly well.

Velocities by the Haskell-Ott combination, however, are considerably deficient, as an inspection of the fifth line of velocities in Table 69 shows. This is undoubtedly due to some change in the relations between the two meters. The Ott meter appears to read lower than it should, according to the ratings, as all the velocities for the combinations which include the Ott meter are low.

It was stated in Section 123 that it was not intended to use velocities determined by the Haskell-Ott combination, because the two screw meters are so much alike in performance that errors become magnified. Hence the velocities by this combination are untrustworthy, and should be neglected, except for purposes of comparison.

The problem then narrows itself to the determination of correct average velocities by the separate combinations of the Haskell and Ott meters with the Price.

In the case of the diagrams for horizontal oscillations, it is clear that, if we should wish to alter them by introducing vertical components, the errors of the Price meter would be reduced and those

determined by the diagrams for horizontal oscillations will be too low. There are undoubtedly vertical components of motion in the headwater. Therefore, all the velocities by the diagrams for horizontal disturbance should be too low, rather than too high.

By similar reasoning, it may be shown that, in the case of the diagrams for horizontal and vertical components, if too little oscillation has been assumed for the screw meters in constructing the diagrams, the curve scales will lie counter clockwise from their proper positions. In constructing these diagrams, only the horizontal components have been considered in plotting the co-ordinates for the Haskell and Ott meters. Therefore, velocities by these diagrams, also, will tend to be too low, supposing the correct values of the components have been used in plotting the co-ordinates for the Price meter during the construction of the diagrams.

Moreover, all readings of the meters are likely to be low, as longitudinal oscillations have been neglected altogether. It is not likely, therefore, that any of the velocities in Table 69 are too high.

On the other hand, if too much vertical component has been assumed in constructing the diagrams, the lines would lie clockwise from their correct positions, thus resulting in velocities which are too high.

Now, there was probably not as much vertical as horizontal disturbance in the water, so one element is present which would tend to make the readings by the diagrams for horizontal and vertical oscillations too high. On the whole, it might be assumed, without a serious probable error, that the velocities by the diagrams for horizontal and vertical components will give results which are nearest to the truth.

There will be no serious objection, however, to averaging the velocities in the first four lines of Table 69, as no great differences are involved. In this way a possible systematic error of some magnitude may be reduced. Accordingly, an average of those velocities for each position will be taken as the best probable value.

We are now in a position to compute the factors by which the velocities of the various meters for each position must be multiplied to secure true velocities. The true average velocities at the foot of Table 69 are to be divided by the average velocities of each type of meter from Table 68 to determine the factors. The result is given in Table 70.

TABLE 70.—CORRECTION FACTORS FOR THE METERS, BASED ON THE COMPUTED TRUE VELOCITIES FOR THE FIVE METER POSITIONS IN TESTS *G*, *H*, *I*, *K*, AND *L*, DETERMINED BY PLATES LII, LIII, LIV, AND LV.

(Common discharge = 1 600 cu. ft. per sec. Common area = 625 sq. ft.)

Meter.	Position of Meter.					
	1	2	3	4	5	Mean.
Price	0.994	0.991	0.992	0.972	(0.967) 0.960 (1.179)	0.982
Haskell	1.049	1.059	1.075	1.139	1.222 (1.093)	1.109
Ott	1.034	1.068	1.061	1.100	1.085	1.070
Mean						1.054

NOTE.—The parentheses refer to a possibly more correct value. See foot-note to Table 69.

TABLE 71.—SUMS OF THE TRUE VELOCITIES AT THE 100 METER POINTS IN TESTS *G*, *H*, *I*, *K*, AND *L*, BASED ON FACTORS DETERMINED FROM THE PERFORMANCE OF THE METERS IN THE FIVE POSITIONS DURING THESE TESTS.

Position.	Test.				
	G	*H*	*I*	*K*	*L*
1	505	559	557	502	562
2	524	528	515	516	516
3	503	501	503	501	499
4	541	549	559	555	538
5	(550) 546	(552) 572	(558) 553	(513) 532	(566) 552
Sum of velocities at the 100 meter points in head-race.	(268.3) 267.9	(268.9) 270.9	(269.1) 268.6	(264.7) 266.6	(267.1) 266.7

NOTE.—The figures in parentheses are based on a possibly more correct value for meter velocity. See foot-note to Table 69.

Turning now to the tests in Section 121, it is a simple matter to compute all the sums of the true velocities for the five positions of each test by multiplying the five totals by the corresponding factors from Table 70. This process leads to Table 71, the totals therein being the computed sums of the velocities at the 100 meter points,

based on the factors determined in Table 70 from a comparison of velocities by the different meters in each position of Tests *G*, *H*, *I*, *K*, and *L*.

125.—Velocities in Tests G, H, I, K, and L, Based on Meter Corrections Deduced from Average Meter Velocities in the Five Horizontals in These Tests.—To show that we have a fairly stable method of computing factors for connecting the meter velocities, it will be advisable to compute them for the five horizontals, using the data from the same tests treated in the preceding section. It will not be necessary, however, in the case of horizontals, to reduce to a common discharge and common area, as each meter operates once in each position during the five tests. Variations due to differences in conditions among the tests tend to affect all meters in a similar sense, thus eliminating, on the average, any serious inconsistencies due to this cause. The average velocity for each meter in a given horizontal for all five tests is computed and tabulated, thus leading to a table similar to Table 68. For example, the average velocity in Tests *G*, *H*, *I*, *K*, and *L* for Ott meter No. 1, in Horizontal 1, would result from the sums of the velocities taken from the tests, Section 121, as follows: $(10.98 + 10.32 + 10.00 + 10.94 + 10.30) \div 20 = 2.627$. This figure, rounded off to 2.63, may then be entered in its proper place in Table 72.

TABLE 72.—MEAN INSTRUMENTAL VELOCITIES BY THE FIVE METERS IN THE FIVE HORIZONTALS, FOR TESTS *G*, *H*, *I*, *K*, AND *L*.

Meters.	Horizontal.				
	1	2	3	4	5
P.	2.88	2.91	2.92	2.57	2.39
H_1	2.60	2.64	2.76	2.34	1.77
H_2	2.59	2.78	2.65	2.27	1.84
O_1	2.63	2.71	2.73	2.60	1.97
O_2	2.64	2.67	2.57	2.59	1.96
Average H	2.60	2.71	2.70	2.31	1.80
Average O	2.63	2.69	2.65	2.59	1.97

Just as Table 69 was compiled from Table 68 we may arrive at Table 73 for true average velocities in the horizontals during the five tests.

TABLE 73.—TRUE AVERAGE VELOCITIES DETERMINED BY PLATES LII, LIII, LIV, LV, AND LVI, FROM TABLE 72.

Mean						1.053

* This, of course, is abnormal. A further study would be required to eradicate the error.

Table 74 may then be used to calculate the sums of the velocities for each of the tests, noting that there is only one position in each test for a given meter in a particular horizontal, thus necessitating 25 multiplications to compute each test. We might have compared the meters for the intersection of each horizontal with each vertical position, thus obtaining 25 factors for the 25 meter rectangles in which each meter was operated, but this would have added considerably to the labor of the computation. Undoubtedly, a correction factor

L	268.3

127.—Discharges in Tests G, H, I, K, and L.—Four different velocity computations have now been made for Tests *G*, *H*, *I*, *K*, and *L*. It will be of value to compare these velocities before computing the discharges. Some idea can be gained thereby of the degree of precision attained by the current-meter observations and calculations. The comparison is made in Table 84.

TABLE 84.—AGGREGATE VELOCITIES AT THE 100 UNIFORMLY DISTRIBUTED POINTS IN THE HEAD-RACE OF UNIT NO. 13 FOR TESTS *G*, *H*, *I*, *K*, AND *L*. THESE TESTS WERE NEARLY IDENTICAL AS TO CONDITIONS OF OPERATION.

(Velocities, in feet per second.)

Nature of factors for correcting the meter records.	TEST				
	G	*H*	*I*	*K*	*L*
Based on average velocities in the five positions for Tests *G*, *H*, *I*, *K*, and *L*, reduced to common area and discharge	267.9	270.9	268.6	266.6	266.7
Based on average velocities by each meter in each horizontal for the five tests, *G*, *H*, *I*, *K*, and *L*. Not reduced to common area and discharge	268.8	268.3	270.4	261.0	267.8
Based on average velocities in the five positions for Tests *N*, *O*, *P*, *Q*, and *R*, roughly reduced to common area and discharge	273.6	270.6	268.7	264.4	267.1
Based on average velocities by each meter in each horizontal for the five tests, *N*, *O*, *P*, *Q*, and *R*. Not reduced to common area and discharge	269.3	269.2	271.8	261.6	268.3
Averages	269.9	269.8	269.9	263.4	267.5

By referring to Tables 70, 74, 78, and 82, it will be seen that the average values of the correction factors for all meters are, respectively, 1.054, 1.053, 1.055, and 1.054, among which the maximum variation is found to be not more than 0.2 per cent. As to an average value, the system of factors is very stable.

There are relatively larger variations, however, among the four estimates of the sum of velocities for any individual test. As a general rule, the sum of the velocities for any test is larger when based on factors determined from Tests *N*, *O*, *P*, *Q*, and *R* than when based on those determined from Tests *G*, *H*, *I*, *K*, and *L*, though, on the average, this discrepancy is not large, the total sum for the five tests for the four classes of factors differing only as in Table 85.

TABLE 85.—TOTAL SUM OF VELOCITIES FOR TESTS *G*, *H*, *I*, *K*, AND *L*, BY THE FOUR METHODS.

(Velocities, in feet per second.)

Factors based on tests:	Meters compared by:	Total sum of velocities, all five tests.
G, *H*, *I*, *K*, *L*	Positions	1 340.7
G, *H*, *I*, *K*, *L*	Horizontals	1 336.3
N, *O*, *P*, *Q*, *R*	Positions	1 344.4
N, *O*, *P*, *Q*, *R*	Horizontals	1 340.2

As to individual tests, it will be seen that there are maximum variations for *G*, *H*, *I*, *K*, and *L*, respectively, as follows: 2.1, 1.0, 1.2, 2.1, and 0.6 per cent. Thus, different computations of the sum of the velocities, and therefore of the discharge, may vary by 1 or 2 per cent. The best that can be done by the foregoing computations will be to take the average sum of the velocities for each test at the bottom of Table 84 for the calculation of the corresponding discharge.

Before making the calculation, it must be explained that there are two corrections to be applied to current-meter discharges before the best estimate can result.

128.—Pump Discharge Added to Current-Meter Discharge.—In Section 51 it was shown that the discharge of the centrifugal pump was about 900 gal. per min., or about 2 cu. ft. per sec. As the suction of the pump was up stream from the current meters, and the discharge was down stream, this 2 cu. ft. per sec. must be added to the discharge determined by the current meters in tests where the chemical and meter methods were run in parallel.

129.—Meter-Rack Correction.—It was suspected by the writer that the frame for supporting the meters had a retarding reaction on the speed of the meters, as the framework of the rack formed a considerable obstruction in the head-race.

Three comparative tests were run to determine the amount of retardation, but none was executed under satisfactory conditions, and reliable information cannot now be given concerning the effect in question. However, the tests will be described briefly.

The tendency of the meter rack is to cut off the flow through the obstructed portion of the race and divert it to the unobstructed portion. Therefore, a meter in front of the rack will tend to run slower, and one in the section above or below the rack will tend to run faster, than with the rack removed.

Accordingly, some arms were made for the purpose of attaching the meters to the rack in such a manner as to hold them exactly 2 ft. vertically under their usual positions in front of the rack. A traverse of the race with the meters attached to the arms was then made, after which a traverse was made with the meters in their usual positions. The results of the traverses show that the meters were retarded, but the tests were too limited to give an exact measure. One of the tests is probably excessive and one is deficient in velocity, the mean of the three tests probably being not far from the truth, though it would seem to the writer to be too small rather than too large.

TABLE 86.—Comparison of Velocities at Points in the Head-Race, When the Meter Supporting the Rack Is in the Usual Position, with Those at the Same Points When the Rack is 2 ft. Higher, the Meters Being Then Held on Arms Extending 2 ft. Below the Rack.

Meters on Arms.		Meters in Normal Position.	
Test.	Mean velocity, in feet per second.	Test.	Mean velocity, in feet per second.
24	2.494	25	2.450
71	2.559	70	2.601
72	2.690	73	2.668
Mean	2.581	Mean	2.573

On the average, there is an apparent retardation of 0.3%, due to the presence of the rack.

It may be explained that the meters always operated at the regular meter points in the race, the effect being that the rack was 2 ft. higher than its usual position when the meters were attached to the arms.

The method of suspending and operating the meters is explained fully in Part III.

130.—Computation of Discharge in Tests G, H, I, K, and L.—To obtain the metered discharges for these tests from the average sums of the velocities in Table 84, it is merely necessary to multiply the sums by the distribution factor and the resulting product by the area of the section. By applying additively about 7 cu. ft. per sec., the corrected discharge may be obtained, taking into account the pump and rack corrections. Table 87 results.

TABLE 87.—DISCHARGE IN TESTS *G, H, I, K,* AND *L,* BASED ON AVERAGE AGGREGATE VELOCITIES DEDUCED BY THE FACTORS.

131.—Discharge in Tests N, O, P, Q, and R.—As in the preceding section, the discharges for Tests *N, O, P, Q,* and *R* can be computed from the aggregates of velocity for these tests. Table 88 gives the aggregates for the four systems of factors deduced. The remainder of the calculations will be clearly understood without further remark.

132.—Discharge in Tests S, T, U, and V.—Tests *S, T, U,* and *V* have been computed in the same manner. The final results are shown in Tables 90 and 91.

133.—Comparison of Discharges by Current Meter with Those by Chemical Method.—In making this comparison it must be understood that the tests in which both methods were used were the earlier and less reliable ones, in which there is considerably more uncertainty than in the later (numbered tests following Test 25) series. The

power was measured only by the switch-board instruments, and has been corrected as nearly as may be, but is probably not to be relied on to within 1 per cent. Hence, it is scarcely possible to state in all cases whether the current meters or the chemical method is the more accurate.

TABLE 90.—AGGREGATE OF VELOCITY AT THE 100 UNIFORMLY DISTRIBUTED POINTS IN THE HEAD-RACE OF UNIT No. 13 FOR TESTS *S*, *T*, *U*, AND *V*. THESE TESTS WERE RUN UNDER CONDITIONS WHICH ARE VARIABLE FROM TEST TO TEST.

In particular, Tests *T*, *U*, and *V* are very doubtful as to the chemical method, as it is practically certain that an error was made in the laboratory when titrating the salt-solution samples of Tests *T* and *U*, and leaking pipes affected the results of Test *V*.

It appears that at this time the chemists had not succeeded in titrating all the samples of each test on the same day. Frequently, the salt-solution samples were titrated on the day following the titration of the remainder of the samples, and, in the case of Tests *T* and *U*, these salt-solution samples undoubtedly became interchanged, so as to cause Test *T* to give too great a discharge and Test *U* to give too small a discharge, each by several per cent.

In the case of Test *V*, Sample 22 titrated about 3 c.c. lower than it should, thus pointing to a leak in the corresponding pipe.

By interchanging the values of *v* as used in Tests *T* and *U*, Table 50, the discharges for these tests can be shown to be about 1 662 and 1 513 cu. ft. per sec., much more likely values than those given in the table. If Tests *T* and *U* are to enter into the comparison, these values should be used.

In the case of Test *V*, it is doubtful whether any improvement can be made in the calculation, further than to state that the discharge computed in Table 50 is too large, owing to the dilution of tail-water samples by reason of a leak. To compare methods, therefore, it will be advisable to omit Test *V* altogether.

Of course, the practice of titrating the salt-solution samples at any other than the time at which the remaining samples of the same test are treated is contrary to the principles of group titrations, fully discussed in Section 48, Part II.

The comparison of the discharge by the two methods is given in Table 92.

TABLE 92.—COMPARISON OF DISCHARGES DETERMINED BY CURRENT METERS WITH THOSE DETERMINED BY THE CHEMICAL METHOD.

Test.	Discharge determined by:		Remarks.
	Current meter.	Chemical method.	
G	1 663	1 662	
H	1 662	1 662	The figures in parentheses are corrected from the erroneous results of Tests *T* and *U*, as explained in note at foot of Table 50. They are the only figures which should be used in these comparisons.
I	1 662	1 666	
K	1 618*	1 683	* Meter in fifth position appears to run slower than usual.
L	1 648	1 647	
N	1 785	1 777	
O	1 783	1 768	
S	1 676	1 640	
T	1 628	1 746 (1 662)	Meter rack jammed, delaying meter test, which ended 17 min. after chemical test.
U	1 505	1 440 (1 513)	
V	1 505	1 553	Chemical test untrustworthy. Sample 22 indicates a leak in sampling pipe.

Omitting Test *V*, the total discharges by current meter and chemical method are 16 630 and 16 680 cu. ft. per sec., respectively, results differing by 50 cu. ft., which is 0.3%, on the average, during the tests.

The close agreement between the two methods for several of the tests is more or less of a coincidence, but is significant of the fact that there are no large systematic errors in either method.

Of course, it will be understood that the current-meter computations would have been much simpler had the meter rack been arranged so that direct comparisons of two meters of different types could be made in one and the same test, rather than to have to resort to comparisons in different tests. However, the work is more interesting in its present form.

Before closing, it must be repeated that the tests in which comparisons of the results by meters and chemicals can be made are by far the least reliable of any, excepting possibly a few where leaks in the sampling pipes vitiated the results altogether. Such tests are limited to a few in the series numbered from 1 to 25.

For much valuable advice and assistance of various kinds the writer is greatly indebted to Messrs. T. J. Bostwick, I. G. Calderwood, John R. Freeman, P. H. Falter, E. E. Haskell, George K. Herzog, J. H. James, D. J. Jones, H. W. King, Marks Neidle, H. C. Sadler, I. B. Smith, E. W. Schoder, W. M. White, Gardner S. Williams, I. W. Wilson, A. S. Yount; and the engineers and chemists more or less directly connected with the tests: Messrs. C. E. Andrews, G. H. Bancroft, J. Earle Brennan, J. B. Campbell, Clyde L. Frear, Y. Habeshian, F. G. Hess, J. G. Hinch, J. A. Lahey, W. A. Mudge, M. H. Montross, F. Nagler, A. J. Salathe, Arthur Schweier, C. M. Scudder, G. H. Spencer, M. L. Stack, K. T. Stearns, Thomas Sullivan, C. S. Thayer, D. C. DISCUSSION

Mr. Kershaw.

G. BERTRAM KERSHAW,* M. AM. SOC. C. E. (by letter).—The writer has read Mr. Groat's paper with great interest. With respect to the word, "Chemi-hydrometry", as the author points out, this is a hybrid word derived from the Latin and Greek languages. As salt alone is used for mixing with the water, the writer would suggest the word, halo-hydrometry, derived from the Greek word ἁλς (hals) meaning salt. We already have the term, isohales, or lines of equal salinity, derived from ἴσος (equal) and ἁλς (salt). Halo-hydraulics would not be suitable, as the word ἀυλος signifies a pipe.

Will Mr. Groat kindly explain briefly the "moving-screen" method of measuring large volumes of flowing water, mentioned on page 952. The writer would also like to know whether the salt caused any appreciable frothing of the water when passing through the turbines, and whether there was any tendency of the meters to "short-circuit"?

Has Mr. Groat tried the use of coloring matter in the water in lieu of salt, for example, fluorescin; and does he consider a colorimetric method feasible?

With regard to the "shaking of samples", mentioned on page 1106, it was found necessary, during the taking of some thousands of samples of sewage, tank liquor, and effluent, to adopt a uniform method in order to secure a fairly complete mixture. The individual sample bottles were filled absolutely full, avoiding air bubbles as far as practicable. Actual shaking was found to be far less effective than quietly inverting each bottle for about 5 sec., and then reversing it, the operation being repeated ten times in succession. The absence of an air bubble in this case lengthened the period required for satisfactory mixing.

The writer would be much obliged if Mr. Groat would give the names of the makers of the Ott and Haskell meters; he has used the small Price meter for many years, and has found it to be a most excellent instrument. He has also used the Ekman meter, which is provided with an ingenious compass arrangement whereby the angle made by the head of the meter with magnetic north can be ascertained at great depths. Generally speaking, current meters manufactured in England leave much to be desired.

Mr. Fuller.

GEORGE W. FULLER,† M. AM. SOC. C. E.—It occurs to the speaker that there is one phase of this subject which no doubt has been adequately considered by the author, but which is mentioned in the hope that it will lead to some discussion. Reference is made to the diffusion in water of solutions of chemicals such as salt.

---

* Westminster, S. W., London, England.

† New York City.

Mr. Fuller.

Some years ago, when the speaker was connected with the Lawrence Experiment Station of the Massachusetts State Board of Health, solutions of salt were used to measure the actual period of flow of liquids through sedimentation tanks. The purpose was to ascertain the actual detention period of the liquid in the tank, as compared with the theoretical period obtained by dividing the capacity of the tank by the actual flow into and through it. By the use of salt applied to the entering water, and by tests of the effluent to determine how quickly the salt actually passed through the tank, information was obtained as to the extent which short-circuiting and other factors cause the actual detention period for part of the water to be less than the average or theoretical detention period.

Solutions of salt were also used at Lawrence to determine the water content, that is, the quantity of water held by capillarity in intermittent sand filters, in connection with studies to ascertain the best rate at which to operate the filters. Here, too, solutions of salt were added to the influent, and its rate of travel through the filter was determined by the tests of the effluent, in order to note the increases in salt content above the normal.

At many places, in recent years, in connection with the purification of water and sewage, use has been made of salt solutions and of aniline dyes to develop information along the lines just stated. Obviously, this use of salt solutions is somewhat different from that described by the author. In fact, it deals particularly with liquids moving at an extremely low velocity, whereas relatively high velocities would be used in a head-race in connection with tests of a hydro-electric plant.

However, it may be of some interest to mention that, at Lawrence, the diffusion of the solutions of salt proved to be a bothersome factor; in fact, some salt was found at the outlet of the tanks and filters at an interval so short after its application to the influent as to point most strikingly to the influence of diffusion. It is very likely that the use of salt for the purpose described so interestingly by the author would not involve similar complications, notwithstanding the fact that diffusion is a particularly disturbing element when applied under some conditions, as at Lawrence.

Mr. Peaslee.

W. D. PEASLEE,* ESQ. (by letter).—This classical paper is a very welcome and timely contribution to the literature of this subject, and Mr. Groat's masterly treatment is not a surprise to those who are familiar with his professional work.

However, the writer fears that the very mastery shown by this paper will cause the average engineer to regard what Mr. Groat so aptly terms "Chemi-Hydrometry" with a certain degree of misgiving,

* Dept. of Elec. Eng., Oregon Agricultural Coll., Portland, Ore.

Mr. Peaslee.

in that it would seem, on account of expense and intricacy, to be applicable only to those particular cases wherein the magnitudes and money involved warrant such a precision study as described. Although the degree of research and precision outlined in the paper is, of course, necessary in a test of the magnitude of this one, there is no limit to the field of this method when properly applied.

The writer has been working on this subject for more than 2 years, and although, on account of the high heads and small discharges common in the West, occasion has never arisen demanding the measurement of discharges greater than 300 sec-ft., a method has been developed* wherein several features have been worked out tending toward a greater simplicity of procedure, and sacrificing to only a small degree the accuracy secured by Mr. Groat.

The measurement and maintenance of the dosing rate is secured with the equipment shown by Fig. 40. Various sizes of nozzles, to fit the lower end of the pipe, are made, and the equipment can thus be calibrated for several different dosing rates, maintaining, with the hook-gauge, a constant head over the nozzle. As is well known, a properly designed nozzle orifice is one of the most accurate methods of determining small discharges. With this equipment the stop-watch error is almost entirely eliminated, as the calibration can be made over a long period of time. Also, as the calibration can be made with the dosing solution used, the effect of temperature and therefore of density can be eliminated. It has been found feasible to hold and determine the dosing rate within a total error of 0.1 of 1 per cent.

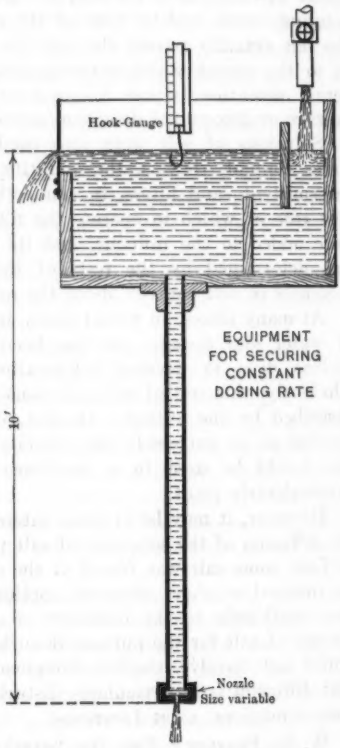

FIG. 40.

* *Journal of Electricity, Power and Gas*, August 21st and 28th, 1915.

Mr. Peaslee.

This equipment has now been in use for several months, in the following rather interesting way: A Central Station Company, carrying a rather large rural pumping load, has equipped an automobile with this apparatus, a quantity of salt, sample jars, electric meters, and a large tank. At certain intervals, two men with this outfit make the rounds of every pump on the company's lines and make discharge measurements of the pumps by this method, and at the same time take electrical input readings. The samples taken are sealed in jars and, with the meter readings, are sent to the chemist at the main office, where they are analyzed. In this way many very valuable data are secured at very small expense to the Company and with no trouble to the pump men. The capacities of the pumps range from 40 to 4 000 gal. per hour, and these two men, now that they are used to the work, can set up and run a test in a remarkably short time. The writer feels sure that the error in the results from these tests is 0.5 of 1% or less.

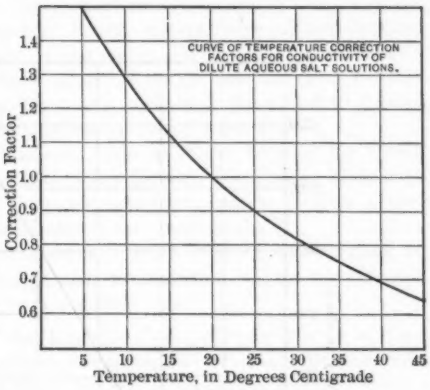

FIG. 41.

The point the writer wishes to bring out is that, especially for small discharges, it is possible, by the sacrifice of a very small degree of the accuracy of Mr. Groat's work, to have a method which will not appear to the average engineer as formidable as Mr. Groat's paper would suggest; and is, at the same time, cheaper than almost any other determination, and more accurate than most test conditions warrant.

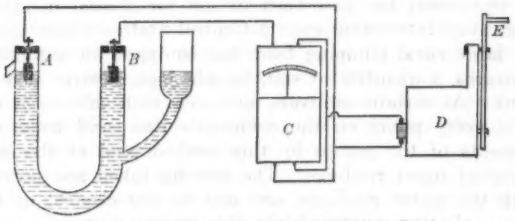
As there is only a very brief reference to the electric method of determining the salt content of samples, the writer will add a short description of some work he has done, using this method.

The following factors enter into and must be taken account of in any method involving the electrical determination of the salt content of samples:

1.—Temperature has a distinct and accurately known effect on the electrical conductivity of any saline solution. The curve of Fig. 41 shows this variation as it has been determined experimentally, verified by mathematical computation based on chemical theory.

2.—There is a counter electro-motive force of polarization that must be corrected for or taken into account in the calibration of the

Mr. Peaslee.



APPARATUS FOR ELECTROLYTIC DETERMINATION.

FIG. 42.

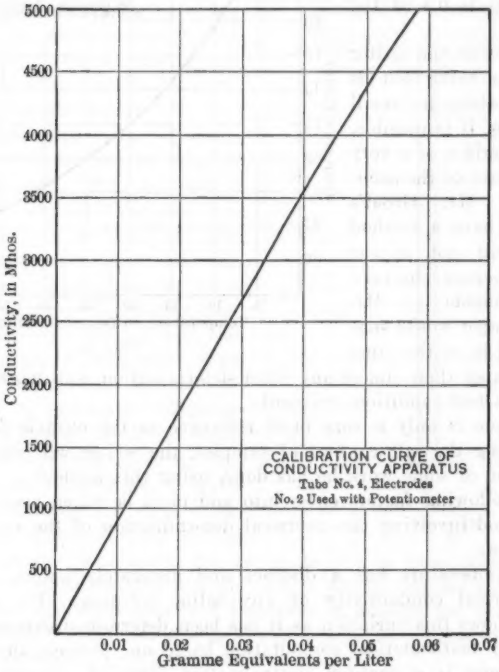


FIG. 43.

apparatus. For weak salt (NaCl) solutions and bright platinum electrodes, this is constant and a little less than 2 volts. Mr. Peaslee.

3.—Means must be provided for thorough cleaning of the apparatus, in order to maintain the integrity of the different samples.

4.—The formation of gas bubbles on electrodes must be prevented, or account must be taken of their effect.

The equipment shown by Fig. 42 has been developed and has proved successful when determinations on the samples within 0.1 of 1% are satisfactory, and further work is being done toward a refinement of this method. In this figure, *A* and *B* are bright platinum electrodes of special design to prevent bubble formation; *C* is a conductivity meter; and *D* is a direct-current generator of suitable design. The whole equipment can be made very compact and portable.

It is calibrated with known solutions, and a curve, such as Fig. 43, is obtained which takes into consideration the variations in cross-sections of the tube, the counter electro-motive force of polarization, and individual characteristics of the meter. With this equipment and the method of special dilutions, much of the tedious titration work is avoided, and the experience of a year's work leads the writer to depend on this method and equipment to within 0.1 of 1 per cent.

The field of this method is very wide, as it can be used for cheap, accurate tests on small discharges, up to, say, 500 sec-ft., and, with a corresponding increase in expense and care, can be used as a precision method on discharges of almost any magnitude.

The engineering fraternity owes a large debt of appreciation to Mr. Groat for his remarkably able presentation of the theory and practice of this method in such complete form.

W. L. Waters,* Esq. (by letter).—This paper covers in a very complete and thorough manner the technique of conducting an efficiency test on hydraulic turbines by the salt-solution method, but, in view of the great detail of the tests, the writer thinks that Mr. Groat could, with advantage, publish some additional figures in connection with the readings. Mr. Waters.

The principle of this test with a salt solution is that brine added to the water in the forebay becomes uniformly mixed with the whole water supply of the turbine. It is evident that, if the efficiency of the forebay and turbine were 100%, there would be no eddies in the water to enable the brine to mix and form a solution of uniform density with the whole of the water supply. The brine, when added in the forebay, would simply move in stream lines parallel to those of the water supply, so that it would not mix.

In each test, Mr. Groat takes eighteen samples of the tail-race water, and it is probable that a comparison of the figures obtained

* Pittsburgh, Pa.

Mr. Waters. for each of these eighteen samples would give a very fair idea of the extent to which the brine solution becomes uniformly mixed with the forebay water in the average high-efficiency modern turbine.

If it is found that the brine does not mix very satisfactorily in an efficient turbine, it would indicate that difficulties may be expected in applying this otherwise very attractive test to the case of turbines with a very high efficiency. It is probable that the figures obtained by Mr. Groat will enable a fairly definite opinion to be formed as to the degree of mixing obtained, if the results obtained in each test of the various eighteen sample tubes in the tail-race are given. On this point Mr. Groat could add greatly to the value of the paper if he would give some additional test figures.

Mr. Horton. ROBERT E. HORTON,* M. AM. SOC. C. E. (by letter).—Any one who has undertaken an original investigation in a new field must realize the enormous amount of painstaking and careful labor which has been involved in the preparation of Mr. Groat's paper. On looking it through, it appears that he has presented the original data fully, freely, and without reserve, thereby setting an example which may be properly followed by others offering the results of original investigations. As a rule, even though errors may be found, the results of such an investigation are likely to inspire greater confidence, and are certain to be more useful in assisting future progress in the work if presented in full, as has been done here.

The author suggests the use of the term "chemi-hydrometry" to describe the measurement of the volume of flowing water by the introduction and subsequent detection of chemicals. As he suggests, this name is not very satisfactory. The terms "hydrometry" and "hygrometry" have been pre-empted, unfortunately, to describe somewhat limited special aspects of the measurement of water. There is great need for some term to cover all classes of measuring water, itself an art of far-reaching importance. In fact, there is need for a general revision of hydraulic terminology. The term "hydrography", sometimes used to describe the measurement of water, should be limited in its application to the mapping of waters, giving it a meaning somewhat analogous to the words "topography" or "geography" in relation to the mapping of lands. Hydrology, in its broad sense, covers every aspect of the science and phenomena of waters, but should generally be used in the more restricted sense of the science covering the laws and phenomena of occurrence and distribution of waters in their natural state. It would thus include the phenomena of precipitation, evaporation, yield and regimen of streams, and the flow of groundwater. In this sense, the word "hydrology" is akin to the word "geology" in relation to the solid materials of the earth.

* Albany, N. Y.

Mr. Horton.

The writer suggests the use of the term "aquametric", as being both available and expressive, to describe matters relating to the measurement of water in general. Thus an aquametric survey would be a survey for the purpose of determining the quantities of water in a region. In the present instance, as the measurement is accomplished by the use of salt, the process might be denominated a "sal-aquametric" method.

Regarding the current meter, the writer believes it is a much abused instrument, and, at the same time, its value and utility are often greatly over-estimated. Under suitable conditions, it may quite certainly give results of a single measurement of a stream accurate within less than 1 per cent. This would require that the channel be of sharply-outlined, definite, and well-determined cross-section, and that the stream should be flowing below the critical velocity, so that stream-line, or filamentous, flow takes place. The writer concluded some years ago that there was danger in accepting current-meter ratings made in still water as being always applicable to flowing water. Until recently, the reasons for this do not appear to have been set forth satisfactorily. A recent book* shows logically and conclusively that errors such as have been referred to might exist, and that their cause rests essentially in the difference in fluid resistance under conditions where the fluid is static and the object is moving, as compared with the resistance where the object is quiescent and the fluid is moving in a non-uniform or sinuous manner. Experiments on the flow in pipes show that the critical velocity at which motion changes from the stream-line system to the vortical flow is not the same when the fluid velocity is gradually increased, as it is when the velocity is decreased from a higher to a lower limit.

As illustrating the conditions under which highly accurate results may be obtained with a current meter, Fig. 44 is presented, showing the velocity contours in a cross-section of a flume, of smooth, planed plank, specially constructed for the purpose of measuring the stream, the velocities being taken with a current meter suspended from a framework in such a manner that the exact position of the center of the meter could be determined with a high degree of accuracy.

As an illustration of the uncertainties of current-meter work unless proper precautions are taken, the writer recalls an instance which occurred a number of years ago. A dam was being used as a weir for the purpose of measuring the yield of a stream on which a power plant was to be constructed. It was known that there was considerable leakage through the dam, and an attempt was made to determine the volume of this leakge in the early winter, at a time when there was some water flowing over the crest of the dam, and it was impossible to draw the water down to crest level. There was a masonry aqueduct

* "The Motion of Liquids," by R. De Villamil.

Mr. Horton.

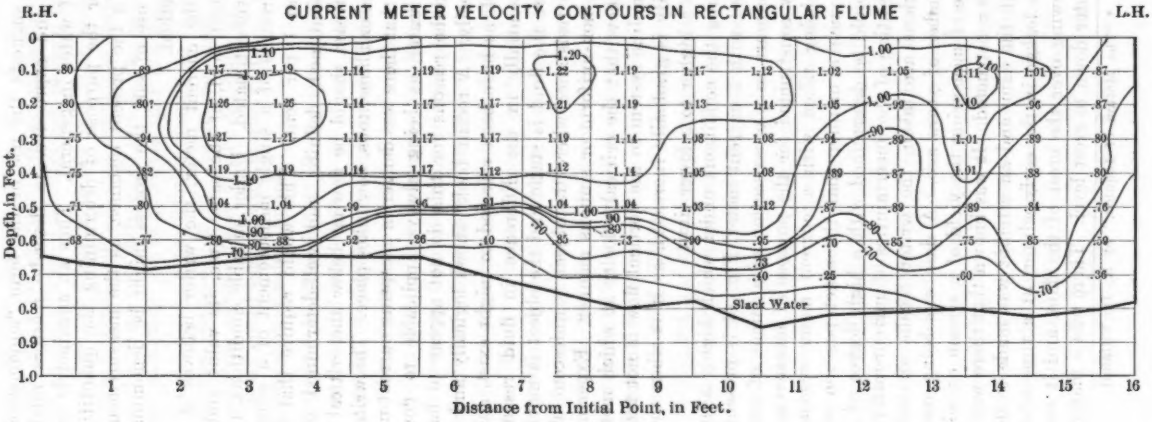

FIG. 44.

Mr. R. Horton.

across the stream a few hundred feet below the dam. This aqueduct had about a dozen archways, and was constructed with a parapet over which one could look vertically down to the water surface, but it was impossible from any position on the aqueduct to look under the archways. The idea was to make a current-meter measurement of the flow under this aqueduct, subtract from the measured flow the calculated flow over the spillway, the remainder being the indicated leakage through the dam. The writer is informed that the measurements were made by current meter in the usual manner, and that from surface indications there was apparently a uniform current at right angles to the aqueduct passing under each archway. The stream was probably turbid at the time, so that it would have been impossible to observe the position of the submerged meter had an effort been made to do so. These measurements indicated an apparent leakage through the dam of 315 cu. ft. per sec., which the writer is informed was accepted as a basis for estimating the low-water flow of the stream in connection with the proposed power development. Being suspicious of these results, the writer undertook to make an independent determination of the leakage through the dam in the following summer. Examination of the aqueduct showed that most of the leakage came down the right-hand side of the stream; reaching the up-stream side of the aqueduct, the current was deflected across the stream, and the flow finally passed out under the left-hand arch. The deflection of the current was caused by the existence of old falsework under all the archways except the one on the left-hand side of the stream. At the time the writer's observations were made, the water was drawn down to the crest of the dam, but further observations showed that, when there was a sufficient volume of water wasting over the dam, the water would spill over the obstructions under the archways in such a manner that there was an appreciable surface current directly down stream, although the main flow was across the stream channel. Apparently, the current meter had been headed across the stream, and the same water had been measured over and over again, as careful measurements by wading, where the leakage through the dam was concentrated in a single channel, indicated the actual leakage at crest level to be only from 35 to 45 cu. ft. per sec.

The power development based on the erroneous measurements was a failure. The writer had nothing to do with the original measurements, and did not receive any very cordial thanks for calling attention to the error, as the owners of the proposed power development were just at that time attempting to issue additional bonds to complete their construction.

Sal-aquametric turbine testing is evidently laborious, requires a great refinement of methods, and is costly. There appear to be many situations where it would be difficult to apply this method in

Mr. Horton. practice. The same may be said of any other method of water measurement in particular cases. Therefore, no single aquametric method should be either universally condemned or accepted to the exclusion of all others.

Mr. Wiggin. THOMAS H. WIGGIN,* M. AM. SOC. C. E.—The author is to be praised for the care with which he has worked out all sources of error. Probably some of these errors would never require attention in ordinary tests; but it is well to know the sources of even small ones and to have them explained so that they may be avoided. The speaker has had something to do with testing machines, and knows how easy it is for errors to be overlooked. For example, on so simple an apparatus as a mercury gauge for showing heights of water, there are several sources of error which are commonly neglected, and could amount to quite a percentage. The speaker remembers one pumping engine test where unusual care was taken, there being a good-sized bonus in question, but in which one source of error which was not taken into account amounted to several thousand dollars.

The question intrudes itself, however, as to whether it is ever justifiable to write a specification in which the degree of accuracy indicated by the author is attempted; in other words, whether the cost of testing is not more perhaps than the amount involved, and whether still further refinement might not prove the apparent precision to be in part fictitious. Furthermore, is the quantity to be measured—namely, the efficiency of the turbine—sufficiently constant for a considerable period of time to justify such precision? It would be of interest if the author could state whether, after a week, 10 days, or a month, this same machine, tested to the same accuracy, would show the same efficiency. Perhaps the author can tell of tests conducted at intervals on the same turbine which would show whether the machines changed.

A water-works engineer is glad to get a Venturi meter in his line which will enable flows to be measured to within 1% or so; but it is not always possible, and occasions come to the speaker's mind in which the author's method of measuring flows will be indispensable, particularly when it is reduced to its simplest terms. The speaker presumes that the actual performance of such tests, now that the author's exhaustive investigation has been completed, will be much less formidable than is indicated by an examination of the paper and the illustrations.

The cost of these investigations must have been considerable, and the author and others who have generously contributed the results to the Engineering Profession deserve thanks and appreciation. It would be of interest if the author could state, roughly, the probable cost of a future test conducted with the care indicated, now that the method has been established; also, for purposes of comparison, rough figures

* New York City.

for the commercial value of small increases in turbine efficiency, justifying extreme precision in such tests. Mr. Wiggin.

W. S. RICHMOND,* M. AM. SOC. C. E. (by letter).—The excellent use which Mr. Groat has made of his exceptional opportunity to carry on experiments in hydraulic measurements, while performing important hydro-electric tests, is highly commendable. It would seem that every item of the work had been considered, experimented upon, and discussed, in so far as it was at all pertinent. The paper is a very valuable addition to hydraulic literature. Mr. Richmond.

Mr. Groat remarks that in some cases, where apparently excellent current-meter work has been done, the results are chargeable to art as much as to science. With this idea the writer agrees, and he believes the fact is not objectionable, as he understands the author's remark to indicate. Long familiarity with the Haskell meter has convinced the writer that its use and care involve as much of art as of science in those instances where it is made to give the best account of itself, exactly as is the case in the delicate manipulation of a transit or a ruling-pen.

The writer had the great pleasure of spending an hour with Mr. Groat at Massena in 1914 while the tests were in progress. He did not see any current-meter measurements being made, but did see the gauging sections, and was permitted to examine the current meters. The writer then felt that the author had before him a difficult task in both the chemical and the current-meter gaugings. On the one hand, conditions of low head, large volume of flow, and short distance between dosing and sampling sections appeared disadvantageous for the chemical gauging; and, on the other hand, the sections necessarily chosen for the current-meter observations were obviously poor. Moreover, the chemical gauging was pioneer work. So far as the writer's knowledge goes, the only other instance of chemical gauging of importance in connection with the testing of hydro-electric generating units in America is that by Mr. Abraham Streiff for the Fargo Engineering Company, at the Croton power-house, on the Muskegon River, in May, 1914. The agreement of discharge measurements by chemical and by current-meter methods there is reported to have been 1.3 per cent. Great credit is due to Mr. Groat for obtaining such accuracy as he has in the chemical gauging, and he is to be congratulated on the excellent apparent agreement of results by chemical and current-meter methods.

The author states that the rigid method of support is very unfavorable to the Haskell meter, and that it is favorable to the Price meter. This is strikingly shown in the results of the experiments performed in the Naval Tank at Ann Arbor. The large errors introduced in

* Detroit, Mich.

Mr. Richmond.

the case of the Haskell meter are surprising, and indicate clearly that this method of support should not be used if it can be avoided. During the work at Massena in 1911 the meters were provided with tails, and were supported by rods or cables in such a manner as to be free to swing both horizontally and vertically. The results then obtained at very poor sections showed comparatively small errors in the Haskell meter, and rather large errors in the Price meter. The conclusions then reached were in general harmony with those of the writer, who has used only meters provided with tails and suspended by cables. In this case the angle which the meter makes with the perpendicular to the section at the same point must be measured with sufficient accuracy, and the proper correction applied where necessary. That none may be misled, it seems proper to point out that no errors will result when a Haskell meter, provided with a tail and suspended by a cable, is used carefully at a really good section. That the head-race section at Massena was very poor is shown with sufficient clearness by those observations in the double vertical, No. 5, where the divergence between Haskell and Price meters (assuming no change in still-water ratings) indicates a transverse component of velocity approximately one-half as great as the axial component.

The writer cannot agree with Mr. Groat that "under the most favorable circumstances" current meters may indicate velocities in error by 2 to 8% or even more, when an ordinary still-water rating is assumed to apply. Haskell and Price meters used by the writer have shown no such errors, except when used under unfavorable circumstances, and the error of the Haskell meter has been small under very unfavorable conditions. The writer has used the small Price meter when it over-registered by 34%, and the Haskell meter when it under-registered by 7%, but the conditions had been made exceedingly unfavorable purposely. The maximum error observed by the writer while actually gauging stream flow was approximately 11% for a large Price meter, well rated and in good condition, but suspended from a catamaran which was pitching in a sea so as to give the meter a vertical motion of 3 or 4 ft. amplitude. Under similar circumstances, the error of the Haskell meter has been too small to be determinate. Either meter will frequently give errors of from 1 to 2% in a single short-run measurement, but, under favorable conditions, the mean of several measurements will be the true velocity that obtained, within a fraction of 1 per cent. The writer firmly believes that a B-type Haskell meter, in fine condition, skillfully used, in smoothly flowing, reasonably clear water such as obtains at well-chosen gauging sections on the large streams of the Great Lakes system, may be relied on to indicate the true velocity within a fraction of 1% when its still-water rating is applied, provided the velocity is

Mr. Richmond.

more than 1½ ft. per sec., and the mean of several runs is taken. A Haskell meter frequently will not remain in such a condition long, without attention, and it is necessary to use another meter, or some other equally accurate device, simultaneously, in order that instant knowledge may be had that something is wrong, so that the trouble may be remedied at once. In most of the work of the U. S. Lake Survey, three or more meters have been used on any piece of gauging, two meters being operated simultaneously at the same elevation a few feet apart. By changing meters frequently, and pairing them in as many combinations as possible, it is usually easy to tell which, if any, have changed their ratings, either temporarily or permanently. This has been called the "two-meter method", and, the writer believes, was devised by F. C. Shenehon, M. Am. Soc. C. E., formerly of the Lake Survey, and now of the University of Minnesota. In all Lake Survey work the Haskell meter has been used with tails on the body of the meter and on the weight, the meter being suspended on a flexible cable. This method the writer heartily recommends.

That the still-water rating is applicable without correction in the case of the Haskell meter when used at a good section has been demonstrated in several different ways by the work of the Lake Survey. Perhaps the best test was that made in 1906 in the Detroit River by Mr. Shenehon, under the general supervision of Mr. Haskell. In these experiments, two very stable, light-draft, catamarans were anchored in the river in tandem, being held at a certain distance apart by wires. A Haskell meter was suspended 12 ft. from the side of each catamaran, and 1 ft. deep, the two meters being in the same current thread, one 205 ft. down stream from the other. Liquid blueing was injected into this current thread several feet up stream from the up-stream meter, and carefully timed over the distance between the meters, while the meters simultaneously recorded their revolutions electrically. Seventy-six such observations were made, the mean velocity being 2.862 ft. per sec. by the bluing, and 2.859 by the meters.*

Another proof is furnished by the simultaneous use of Haskell and Price meters in the St. Clair River in 1909. The writer was not then familiar with the experiments by C. H. Miller, M. Am. Soc. C. E., and was considerably chagrined at the time because the meters did not always agree. He soon noticed that the principal discrepancies occurred on those days when the observing catamaran had a vertical motion, due to waves on the river, and that the divergence between the meters increased with the vertical motion. It was found that the measurements by the Haskell meters, when related to the corresponding stage and slope of the river, satisfied very closely the equation expressing the mathematical relation of discharge to stage

* This test is described more at length in Senate Doc. 105, 62d Cong., 1st Sess., pp. 72–74.

Mr. Richmond.

and slope, and that the discharge measurements by the Price meters were too great. This equation had been derived from the results of a great many measurements, most of which had been made under smooth-water conditions, so that the equation itself contained no appreciable error from this cause. Furthermore, on comparatively calm days, simultaneous measurements by the Haskell and Price meters agreed within about 1 per cent. Mr. Groat has shown that in such case the true velocities lie between the values by the two meters. In 1910 the writer made oscillation experiments at a rating base and at one of the hydraulic sections, the results agreeing closely with those obtained by Mr. Groat at Massena in 1911, and showing that a much larger correction must be applied to the Price than to the Haskell meter indications. The Haskell meters, therefore, probably were correct within less than 0.5 per cent.

A third proof was obtained in 1914 at a gauging section on the St. Lawrence River, using a Pitot tube simultaneously with a Haskell meter. The Pitot tube was in general patterned after that recommended by W. M. White,* M. Am. Soc. C. E., and also used by Mr. Groat at Massena in 1911. This tube has been shown by both these gentlemen to give very accurate velocity indications in a current. The writer also made careful experiments confirming their opinions concerning the accuracy of the static orifice. Several sets of simultaneous observations with Haskell meters and the tube were then obtained in a very smoothly flowing current of about 4.2 ft. per sec. The mean result showed the meters in agreement with the tube within 0.4 per cent.

As an indication of the precision that may be obtained in current-meter gauging of large rivers, it may be stated that three separate sections on the St. Clair River, many miles apart, and of entirely different characteristics, showed mean agreements of discharge within 0.4% when compared through the relations of discharge to stage and slope. Similarly, three sections on the Niagara River showed an outside agreement of 1.3%, and two sections on the St. Lawrence River agreed within 0.4 per cent.

Mr. Groat.

BENJAMIN F. GROAT,† M. AM. SOC. C. E. (by letter).—Mr. Kershaw's suggestions as to the use of the term "halo-hydrometry" are worthy of consideration; but the term is narrower than chemi-hydrometry, and thus fails to include chemicals which are not salts—acids, for example. Chemi-hydrometry includes color, conductivity, or any other property which can be changed by the introduction of a chemical.

The moving screen has been used in Europe to some extent, and has been proved to be more accurate than any other method of measuring large volumes of flowing water, with the exception of chemi-hydrometry, which may be made as accurate as desired, with suffi-

* *Journal* of the Association of Engineering Societies, Vol. 27, August, 1901.

† Pittsburgh, Pa.

cient care and expense. A full explanation of the method may be found in a paper entitled "The Diaphragm Method for the Measurement of Water in Open Channels of Uniform Cross-Section",* by Carl Robert Weidner, Assoc. M. Am. Soc. C. E. Mr. Groat.

The method requires a diaphragm which fits the cross-section of a prismatic conduit, or flume, as closely as practicable. This screen traverses the length of the conduit on a carriage which rolls on wheels guided by a track. The volume described by the screen in any observed period of time is theoretically equal to the volume of water flowing in the conduit during the same interval, supposing the screen to move with the average velocity of the water.

Concerning the action of the salt on the feed-water, the salt, being in very dilute solution, caused no "frothing" of the water when passing through the turbines, and there was no short-circuiting of the meters due to its presence in the water, although attention was called to its action on the water rheostat when it was used in Test No. 105. (See Section 109, concerning the first series of tests of Unit No. 11.)

The writer has used color in a series of tests with very satisfactory results. Colors may be matched accurately with a colorimeter, but there is no colorimeter specially adapted to the requirements of chemi-hydrometry, the need of which is suggested at the close of Section 39. The principal objection to color is its cost.

The Ott meter is made by A. Ott, Kempten, Bavaria. The Haskell meter is made by E. E. Haskell, M. Am. Soc. C. E., Cornell University, Ithaca, N. Y. The deep-sea Haskell type gives the velocity and direction of flow at any depth.

Mr. Fuller describes very interesting tests to determine the detention period for liquids flowing through tanks, and to determine capillary volumes by means of salt solutions injected into the influent and measured in samples of the effluent. It is very apparent that diffusion may have a considerable effect on the results thus determined where the velocity of diffusion is large relative to the velocity of the water, or other liquid, into which the salt is injected.

In the case of turbine tests, however, the velocity of the water is relatively high, and the mixture is so nearly perfect that the effects of diffusion are small; in fact, diffusion assists the rate of mixing, and produces a more uniform mixture than could otherwise be obtained. When the mixture is perfect, there is no diffusion.

The writer does not share with Mr. Peaslee the fear that engineers will imagine that they must duplicate all the detail of the work which was undertaken in order to develop a theory and method for chemical testing. It is very easy to see, for example, that the chemical method may be applied with great simplicity to the test of a centrifugal pump, as described in Section 51. It will be observed, of course, that

* *Bulletin* of the University of Wisconsin, No. 672, 1914.

Mr. Groat. no evaporations are necessary in this and similar cases, and that the necessary chemical equipment consists of a comparatively small salt-solution tank connected to the suction of the pump, with means for measuring the weight or volume of the solution consumed, and a very simple outfit for taking and treating the samples from the discharge.

In the case of larger operations, the tests need not be any more complicated, except that where great accuracy is required with large volumes of water to be measured, it will be found advantageous, in the majority of cases, to resort to evaporation for the purpose of concentrating the samples. About the only real difference between the test of a turbine and the test of a pump lies in the magnitude of the operation, which varies to a less relative extent than the quantity of water measured. Nor is it expected that the reader will necessarily adopt the detail of any of the methods treated in this paper. Engineers are capable of planning their own tests. What they want is reliable theory and reliable information on which to base their calculations, estimates, and specifications, without the necessity of experimentation. It was this want that led to unusual efforts in the tests which form the subject of the paper, and the writer will indeed feel satisfied if it is considered that he has, in some measure, supplied the deficiency.

Mr. Peaslee's testing automobile is very interesting. There are, no doubt, many opportunities for the use of automobiles in transporting testing equipment from place to place, and it would seem that there is no reason why the titrations could not be performed on the spot by the men who execute the remainder of the test of any particular pump. With very little practice any engineer can make a titration to 0.1 or 0.2 of 1% by following, in a general manner, the directions in Sections 88 and 89. It should be remembered that the proper rate of draft for titration from an ordinary 75 or 100-c.c. burette is 8 or 10 c.c. per min.

Mr. Peaslee's description of his electrical equipment is very acceptable, as there are few papers, especially in English, on conductivity as applied to chemi-hydrometry. It might be remarked that with the application of the method of special dilutions, or balanced samples, Section 40, it will not be necessary to calibrate the instruments, as the procedure there described eliminates all the instrumental errors. In order to eliminate by special dilutions the effects of temperature, care must be taken to have each pair of tail-water and special-dilution samples at the same temperature. This follows as a corollary from the principle of balanced samples enunciated in the second paragraph of Section 12. One-tenth of a degree will affect the conductivity appreciably. With the exercise of care and judgment, the other errors, also, will be eliminated by a rigid application of the principle.

Mr. Waters asks for additional figures in connection with the readings, apparently referring to the readings for each of the eighteen tail-

race samples taken in each test. The writer has published these in full detail on pages 1182 to 1204, inclusive; and, in Section 50, one of the tests has been examined with respect to the distribution of salt among these eighteen samples. Mr. Groat.

The chemical data of each test have been given in full so that any one can make such study and analysis of them as he may desire, and the results of an investigation of this kind would be welcome. It is quite possible that there may be an error of computation in some of the discordant tests, which could be discovered in this manner. The writer would appreciate being informed of any such discovery.

Mr. Waters is correct in his theory that it should be relatively more difficult to obtain a perfect mixture with relatively high turbine, or pump, efficiency. Practically, the power required in mixing must be very small. Imagine, for example, a barrel of 200 liters of water with, say, 20 "stream lines" or "pencils" of salt solution uniformly distributed in vertical positions throughout the volume. Let a man mix this with a single vigorous double stroke of a large churn dasher, which is then quickly removed from the barrel. One can scarcely doubt that in a few seconds after removing the dasher the mixture will be near to perfection. If not in a few seconds, then certainly within a minute, about the time required for the mixture to pass through the turbine from the sprinkling pipes to the sampling pipes.

The energy exerted by the man can probably be represented by an average of 10 lb. acting 2 ft. downward and then 2 ft. upward, say, 40 ft-lb., or 40 ft-lb. is sufficient energy to cause 200 liters of water and salt to mix while it is flowing from the sprinkling pipes to the sampling pipes. To mix 50 000 liters, the turbine discharge per second, would require 250 times the energy above calculated, or 10 000 ft-lb. If this amount of energy is supplied each second, the entire discharge of the turbine will be thoroughly mixed before it reaches the sampling pumps, and it is easy to see that the power required is about $10\,000 \div 550 = 18.2$, or less than 20 h. p., to mix the discharge of a 6 000-h. p. turbine. In all probability, the eddies generated by the flow of water through the trash racks and against the sprinkler pipes in the head-race are sufficient to cause the necessary mixing of the salt with the feed-water, and the mixing will be aided by any diffusion which may occur.

Mr. Horton suggests the term "aquametric" as one descriptive of matters relating to the measurement of water in general. This term, like chemi-hydrometry, is hybrid, and does not appear to furnish a very euphoneous noun. Aquametry is constructed of Latin and Greek roots, the pure Greek synonym being, simply, hydrometry. It does not appear that there should be any serious objection to the broader use of the term hydrometry, even though usage has given it a more restricted meaning in relation to density and specific gravity.

Mr. Groat.

It was not the writer's intention to present primarily a paper on the current meter, but the methods used in correcting the indications of these instruments, and especially the composite ratings, were thought to be of sufficient interest to be presented in full.

In another series of tests it would be advisable to have readings by the two meters compared at each meter point. This would render the work of reduction much simpler, and be more satisfactory when it is desired to compute the discharge in each individual test. However, it will be observed, when treating all five of the tests in any series as though they were a single test, that the four methods of correcting the discharge give results which agree very closely, as may be seen in Table 85, where the difference between the maximum and minimum aggregates for Tests *G*, *H*, *I*, *K*, and *L*, as determined by the four methods, is only 8 in 1 340 or 0.6 per cent. That the agreement is not a mere chance may be demonstrated by comparing, in similar manner, the aggregates of velocity for Tests *N*, *O*, *P*, *Q*, *R*, as determined by the four methods, Table 93 giving the results for comparison.

TABLE 93.—AGGREGATE VELOCITY FOR TESTS *N*, *O*, *P*, *Q*, *R*, BY THE FOUR METHODS.

(Velocities, in feet per second.)

Factors based on tests.	Meters compared by:	Aggregate velocity.
G, *H*, *I*, *K*, *L*	Positions	1 471.5
G, *H*, *I*, *K*, *L*	Horizontals	1 469.0
N, *O*, *P*, *Q*, *R*	Positions	1 475.0
N, *O*, *P*, *Q*, *R*	Horizontals	1 471.4

In all probability, the individual tests, when computed by the four methods, would have compared about as well as those shown in Table 93, had it been possible to compare the records of meters at a given point in the same test. It will be observed that there are small systematic errors among the four methods. In this respect Table 85 seems to be quite consistent with Table 93.

The writer attributes the principal part of the deviations of current-meter ratings to the difference which exists in the condition of the water during the rating and at the time of the discharge measurement, and considers these deviations to be due only slightly to the fact that the meter is towed forward during the rating and held at a point during the discharge observations. In other words, he does not believe that there is any material difference in the hydraulic resistance of a liquid on a body, whether that body moves through the liquid or the liquid moves about the body, supposing the actual dynamic condition of the water, relative to the body, to be the same in the two cases.

Mr. Wiggin is very properly cautious as to the degree of accuracy of turbine tests, especially as to the possibility of apparent precision being in reality more or less fictitious or imaginary. When a whole series of tests is highly self-consistent, it may be safely concluded that the observations were made with a correspondingly high degree of precision as regards accidental errors. The theory of errors usually presented in treatises on probability, however, says nothing at all about systematic errors, which, indeed, are the errors most to be feared, as they are generally masked or otherwise hidden, so as to be easily overlooked. Mr. Groat.

As to the proper degree of accuracy to be required in turbine tests and the constancy of turbine efficiency, Mr. Wiggin and the writer seem to have somewhat divergent views. From numerous power capacity tests and a number of complete tests where the discharge was also measured by the writer at different times, turbine efficiencies have been found to remain remarkably constant when the machines have been kept in uniform condition and not allowed to become damaged. There seems to be no reason to believe that there are any material variations of this sort in actual practice where the condition of the machinery is well maintained. Good evidence to this effect may be found in the three series of tests on Unit No. 13. These tests extended over the period from July 22d to September 2d, inclusive, and no indication of variation in efficiency is observable. Turbines which were tested in 1911 still have the same capacity curves which were determined at that time. The writer is of the opinion that turbine testing, especially as to the measurement of the water, has been altogether too crude, and that the present requirements demand an increase in the degree of precision for the tests.

It would appear that a unit of power gained by an increase in efficiency is more valuable than a unit of power requiring an additional amount of construction. For it brings the same price on the market and requires no investment other than the cost of securing the increase in efficiency, which perhaps involves nothing more than the engineer's judgment in selecting the better of two designs, and thus is obtained without any increase of expense in operating the hydraulic part of the plant. Of course, there may be required a slight increase of cost and operating expenses for the electric part of the plant in the case of hydro-electric developments. Therefore, if a hydro-electric development costing $100 per h. p. is a paying proposition, and additional power can be had by an increase in efficiency, there is no reason why this additional power would not be well worth $100 per h. p. also, supposing that the market will absorb it without being affected. Perhaps it would be satisfactory to divide the gain due to increased efficiency between the purchaser and the turbine maker by letting the bonus be one-half of the development cost, due

Mr. Groat.

to the construction of the hydraulic part of the plant, including dams, canals, gates, flowage rights, etc. Great caution should be exercised in specifying turbine performance where power is to be developed by means of high efficiency. It would be very easy, indeed, to test turbines and pay a bonus at the rate of $100 per h. p., or one-half of this, only to find that operating conditions would seldom, or never, admit of working the machines under the conditions which secure this power. In all probability, specifications involving these large rates of bonus should not specify maximum turbine efficiency, but rather the minimum efficiency for a considerable range of probable operating conditions, such ranges of condition, for example, as might be specified by mentioning a definite area on a diagram similar to Plate LI.

There is no reason why chemical tests should be more expensive than tests of other kinds. In all probability, they can be made less expensive, especially for a given degree of accuracy. Turbine tests are more or less costly, because they are very complicated, no matter what method is adopted. It requires a considerable number of observers to obtain the data, particularly where the power is measured electrically. Moreover, a large number of tests are required where any attempt is made to cover the range of operating conditions. These remarks relate, of course, to very large power units. A small machine, such as a Pelton wheel or a centrifugal pump, can be tested chemically, with high precision, for a few dollars. The same is true of a water main, though large sizes may present greater difficulty.

The cost of turbine tests will depend on circumstances and on the methods and details adopted by the testing engineer. With the essential methods of testing well in mind, an engineer should be able to devise his tests and make accurate estimates of the cost. He need not be surprised, however, if he should find his estimate to be in the neighborhood of $5 000 for fifty or a hundred tests on a 10 000-h. p. turbine on a head of 50 ft., though circumstances might reduce this to $3 000, or even less. These costs are supposed to include the cost of electrical instruments and the engineering service necessary to conduct the tests and compute the results. The reason these figures seem high is because the tests are turbine tests, and not because they are chemical tests. Circumstances may run the cost higher still.

The writer remembers Mr. Richmond with pleasure. It is true that the meter sections which Mr. Richmond saw were unusually poor, and it is this fact that makes the meter work more valuable, for it shows what corrections are necessary under such conditions. The writer thinks, however, that the conditions for chemical work were favorable, and that there should not be too great a distance between the dosing and sampling stations. Otherwise, the eddies and dead water will require such a long time to fill with chemical that an ac-

curate test will be difficult or impracticable. In the case of large cross-sections, it is advisable to introduce the chemical from the sprinkling pipes on the down-stream side of the trash racks properly stopped sufficiently to raise a head of 8 or 10 in., thereby securing an almost uniform mixture at the outset. Mr. Groat.

The close agreement between some of the current-meter and chemical tests published in the paper is probably more or less accidental, but the writer is led to the belief that current meters can be used successfully in the manner described, so as to secure a degree of precision within 1%, if this was not actually secured in the present case.

There are two conclusions with which Mr. Richmond disagrees. The writer believes in rigid supports, properly designed, cupped, screw runners, and no tails or rudders, and he states on page 952:

"The uncertainty attending the measurement of large volumes of flowing water by methods heretofore used, under the most favorable circumstances * * * , is * * * , [for the current meter] 2 to 8%, and even higher."

In advocating rigid supports and no tails, the writer had in mind the measurement of turbulently flowing water in sections which, perhaps, might ordinarily be thought to be wholly unsuitable for a discharge measurement. That the discharge can be accurately thus measured in such sections by means of rigid supports and proper methods of correcting the meters seems to be accomplished in the tests, and this where the ordinary method would surely fail by a relatively large amount. Even under favorable conditions, the writer adheres to rigid supports and no tails, and advocates a new type of runner designed so that its record will always give the true integrated component of velocity perpendicular to the cross-section. There is plenty of evidence that the latter design may be effected without much experimentation.

The writer's statement concerning the accuracy of current-meter work under favorable circumstances refers to the accuracy of discharges, determined by the meters, and not to tests of the accuracy of the instruments. This is probably the cause of the misunderstanding. Ample authority for the statement can be found in the reports of the Lake Survey engineers. As an example, the interested reader may refer to the Annual Report of the Chief of Engineers on the Survey of the Northern and Northwestern Lakes for 1902, Appendix EEE. The report of F. C. Shenehon, M. Am. Soc. C. E., begins on page 2779, and shows a discharge curve of the St. Lawrence River with limits for errors immediately preceding page 2793. The limit of error is 2% either way, from the discharge curve. These are accidental errors. There is nothing to show that the systematic error

Mr. Groat. may not be larger. Opposite page 2826 will be found a plotting of a discharge curve by L. C. Sabin, M. Am. Soc. C. E., showing errors in the plotted points of several per cent. The report of W. Edward Wilson, M. Am. Soc. C. E., beginning on page 2872, contains a discharge curve of St. Marys Rapids similar to the others. There are many other curves in these reports, and a careful study of them will soon convince any one that errors of 2% are common in current-meter work of the best quality.

In the case of tests of the meters with a quantity of blueing injected into the water and timed over the distance between the two meters, it is gratifying to note the close agreement between the actual velocity and that indicated by the meters. The fact that the ball of blueing remained intact, however, shows that there was little turbulence in the water and, therefore, little cause for errors.

Shrinkage.—As the question of shrinkage will be of importance in many investigations, it will be of advantage to systematize the methods for computing the values of the shrinkage coefficient, and the following remarks will be of interest.

By Equation (63), Section 23,

$$k = \frac{C_2 - C_1 - (D_2 - D_1)}{C_2 D_1 - C_1 D_2} = \frac{d\,(c_2 - c_1) - c\,(d_2 - d_1)}{c_2 d_1 - c_1 d_2} \quad \ldots\ldots(204)$$

Therefore,

$$k = \frac{1 - \dfrac{c}{d}\dfrac{d_2 - d_1}{c_2 - c_1}}{\dfrac{d_1}{d} - \dfrac{c_1}{d}\dfrac{d_2 - d_1}{c_2 - c_1}} = \frac{d}{d_1}\left(\frac{1 - p\dfrac{\Delta d}{\Delta c}}{1 - p_1\dfrac{\Delta d}{\Delta c}}\right) \quad \ldots\ldots(205)$$

where $p = \dfrac{c}{d}$, $p_1 = \dfrac{c_1}{d_1}$, etc., and $\Delta d \div \Delta c$ is the mean rate of change of density per unit change of concentration.

If the reciprocal of this ratio, $\Delta c \div \Delta d$, which is the mean rate of change of concentration per unit change of density, be indicated by α, then it will be easy to show that

$$\left.\begin{aligned} k &= \frac{d}{d_1}\left(\frac{\alpha - p}{\alpha - p_1}\right) \equiv \frac{d}{d_2}\left(\frac{\alpha - p}{\alpha - p_2}\right) \\ &= \frac{d}{d_1}\left(1 - \frac{p - p_1}{\alpha - p_1}\right) \equiv \frac{d}{d_2}\left(1 - \frac{p - p_2}{\alpha - p_2}\right) \end{aligned}\right\} \quad (206)$$

It will be noticed that α is the mean slope, for a given temperature, of a curve on Plate XXXIII, Section 4, with reference to the vertical axis of co-ordinates, for the two points which indicate, respectively, the condition of the solution which is to be mixed with the salt solution

and the condition of the resulting mixture, the symbols p and d, of course, relating to properties of the strong salt solution itself. The second form of the equations is for use with the slide-rule. Mr. Groat.

The formula is perfectly general, and may be used to find the value of k'' by letting the subscripts, 1 and 2, relate, respectively, to the condition of special dilution and the condition of tail-water. Or, the subscript 1 may be changed to accord with the adopted notation, for this case, as follows:

$$k'' = \frac{d}{d'_2}\left(\frac{\alpha - p}{\alpha - p'_2}\right) = \frac{d}{d_2}\left(\frac{\alpha - p}{\alpha - p_2}\right) \quad \ldots\ldots\ldots (207)$$

Here α relates to the slope of the tangent to one of the curves of Plate XXXIII, with reference to the vertical axis of co-ordinates, at a particular point, as there is supposed to be only a very slight difference between the corresponding properties of the special dilution and tail-water at the given temperature, thus bringing the two points indicated by (d'_2, c'_2) and (d_2, c_2) into practical coincidence.

Suppose, for example, that it is desired to ascertain the value of k'' for the usual conditions of a test as given in Table 2, Section 15. The calculation by Equation (207) would then be:

$$\begin{aligned} c_2 = c'_2 &= 0.0591; \\ d_2 = d'_2 &= 0.9984; \\ p_2 = p'_2 &= 0.00006; \\ c &= 290. \\ d &= 1.1837; \\ p &= 0.245; \\ \alpha &= 1.397, \text{ as measured from Plate XXXIII.} \end{aligned}$$

The point where α is measured lies on the line for 20° temperature, as it is assumed that this was the temperature during the usual test. Therefore, by Equation (207),

$$k'' = \frac{1.1837}{0.9984}\left(1 - \frac{0.245 - 0.00006}{1.397 - 0.00006}\right) = 0.977 \ldots\ldots (208)$$

for the greater portion of the tests.

Observe that the calculation may be made with sufficient accuracy with a slide-rule, provided Equation (207) is slightly changed so as to correspond to the second form of Equations (206).

When distilled water is mixed with strong salt solution of a concentration of about 297 grammes per liter, at a temperature of 20° cent., the following results may be deduced by placing $c_1 = 0$, $p_1 = 0$, and $d_1 = 998.23$, in Equations (206).

Mr. Groat.

TABLE 94.—VALUES OF THE SHRINKAGE COEFFICIENT, k, FOR RELATIVELY SMALL RATIOS OF MIXTURE OF A SALT SOLUTION OF 296.98 GRAMMES PER LITER AND DISTILLED WATER AT A TEMPERATURE OF 20° CENT. COMPUTED FROM THE DATA OF TABLE 1 AND THE FOLLOWING ELEMENTS:

$d = 1\,187.9$, $p = 0.25$, $c_1 = 0$, $p_1 = 0$, $d_1 = 998.23$, $d \div d_1 = 1.190$, and $t = 20°$ cent. (calculation by slide-rule).

Approximate value of r	c_2	d_2	p_2	α	k	k''
0.5	197.33	1 127.6	0.175	1.525	0.995	0.999
1.0	148.08	1 096.9	0.135	1.501	0.992	0.997
2.0	101.36	1 067.0	0.095	1.474	0.989	0.994
3.0	73.409	1 048.7	0.070	1.455	0.986	0.992
4.0	57.079	1 037.8	0.055	1.443	0.984	0.990
5.0	51.705	1 034.1	0.050	1.440	0.984	0.988

In computing Table 94, the first of Equations (206) may be put in the following simple form, as c_1 and p_1 are nil:

$$k = \frac{d}{d_1}\left(1 - \frac{p}{\alpha}\right) \quad \ldots\ldots\ldots\

etc., f'' and F'' being, respectively, the ratio of mixture and the ratio of dilution necessary to convert special dilution to the condition of tail-water, in accordance with the definitions and meaning of Equations (14), Section 11, which implies that the special dilution is weaker than the tail-water, or $r' > r$.

But, by Equations (38) and analogy,

$$\left.\begin{aligned} F' = R' \frac{d_2}{d}, f' = r' \frac{d'_2}{d} \\ F = R \frac{d_2}{d}, f = r \frac{d_1}{d} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (213)$$

etc.

Therefore, by proper substitutions, Equations (211) may be transformed so as to give

$$\left.\begin{aligned} r = \frac{r'}{1 + \frac{R'}{r'}} \\ (r' > r) \\ r' = \frac{r}{1 - \frac{R}{R'}} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (214)$$

thus deriving the relations discussed in Section 35.

It is also possible to deduce these same relations by Equations (78), (90), and (91). Thus, for example,

$$r = R' r'' + r' \qquad (r > r')$$

$$r = R' r''$$

Eliminating r'' and solving for r, we have

$$r = r \frac{R'}{R'} + r', \text{ or, } r = \frac{r'}{1 - \frac{R'}{R'}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (215)$$

as before. The remaining relations may be treated in similar manner.

Conclusion.—In closing this discussion, there are a few thoughts which occur to the writer as being worthy of mention.

During the oral discussion, Mr. Wiggin asked for the cost of the tests, with the evident idea that this knowledge would be of value in determining the probable cost of future chemical tests. Unfortunately, the scope of the investigation was so much larger than would ordinarily be undertaken in turbine testing, that a mere statement of total cost without detailed analysis will be of little service for this purpose. The writer would gladly make such a detailed analysis of the cost of the complete series of studies if he thought any useful facts would be

Mr. Groat. brought to light thereby. He feels, however, that this is not the way to arrive at costs. It will be far more satisfactory for the engineer to determine his general method from a study of papers on the subject, afterward arranging the details to suit his own ideas and in conformity with his calculations. His equipment and method for the conduct of the tests thus becoming definite, it will be an easy matter to make accurate estimates of cost. It may be of interest to state that a commercial grade of salt suitable for chemical tests will cost from $1.50 per ton up (depending on the condition of the market), delivered f. o. b. cars, at the salt works.

There are two possible sources of delay and contingent expenses that may exist in connection with turbine tests in place, which it may be well to mention. Where the purchaser and maker each have the right to undertake investigations of their own during the tests, there are likely to be interferences with each other, which are sure to cause more or less delay and repetition, especially if each has a particular line of investigation differing from that of the other; and, where the tests must be conducted without interfering in any measure with the power-house output, methods become restricted, and this leads to an increase in cost.

With the preceding statements in mind, there is no objection to saying that the total cost of experiments and studies involved in the writer's paper was about $18 000. This item includes: The preliminary study; rating current-meters; numerous railroad fares; chemical testing equipment, including tanks, pumps, pipe lines, and laboratory; complete set of precision direct-current electrical testing equipment; complete set of precision alternating-current electrical testing equipment; erecting and adjusting equipment and instruments; supplies and operating expenses in the conduct of the tests; and computations. It does not include the cost of preparing the paper, except in so far as many of the tables are necessarily copies of those derived from the final computations. The writer estimates, roughly, that the value of the instruments and equipment on inventory at the conclusion of the work was $3 500, leaving a net cost of approximately $14 500.

In Section 79, attention is directed to the impropriety of adding the tail-race velocity-head to the elevation of the tail-water before determining the head acting on the turbine. By so doing, the efficiency is made to appear higher than it really is. It is not uncommon to find water issuing from draft-tubes with velocities as high as 15 or 16 ft. per sec. This is equivalent to a head of about 4 ft. If the total head on the turbine was 50 ft., this would cause the efficiency to be overestimated by nearly 9 per cent. If the tail-race velocity were 8 ft. per sec., the head would be reduced by 1 ft. If the head were only 20 ft. in this case, the efficiency would be more than 5% too high. In

making contracts, great care should be exercised not to be misled by incorporating this method of introducing an erroneous head, thereby making the computed efficiency too high. Mr. Groat.

It may be of interest to remark that titrations of salt solution were used in another investigation during the progress of the regular turbine tests. They were used to determine the location of a leak which passed from the bottom of a pond under a dam and into the tail-race of the power-house. The small stream issuing from under the dam could be sampled by simply dipping up the water in a sample container. The strong salt solution was discharged down a pipe from a barrel on a scow which was moved about over the surface of the pond. The pipe was held close to the bottom, and when it was finally placed near the intake of the leak, the titrations of samples taken down stream from the dam quickly indicated the increase of salt in the water.

In another case the location of a leak above a dam was known, and the object of the investigation was to find by means of titrations the subaqueous outlet in the bed of the river below the dam. Thus far, the writer has not received advices of the results.

It may be of value to mention that some time could have been saved in the computations had the calibration of the iron pipette, or tank calibrator, been made in the manner desired by the writer. A large vessel like this, with a contracted pipe or glass gauge at the top, can be calibrated by a scale of temperatures on the gauge so that it can be filled to contain a fixed volume whatever the temperature. This can be accomplished by graduating the scale of temperatures so that each division mark is at the proper elevation for the water surface at that temperature to correspond to the given volume. It is evident, then, for a metal vessel, that the temperature scale will begin at the top and run downward with increasing temperature. Through some misunderstanding, the temperature scale ran upward, the operation, therefore, resulted in a colossal thermometer instead of a convenient calibrator.

In the rules for the chemical laboratory, Section 88, it was said that the proper rate of draft from a burette was about 2 drops per sec. This is scarcely true for all burettes, as the sizes of the tips vary, and this changes the size of the drops. A better rule would state that the proper rate for the draft from an ordinary 75 or 100-c.c. burette is 8 or 10 c.c. per min.

Salt attracts moisture, and is likely to cake and harden when dried. One or two rough drying tests indicated that the low grade of commercial salt used in the tests carried about 6% of moisture. In other cases, a different result might be found.

The color intensity method of chemi-hydrometry should be distinguished from the method of determining mean velocity by observing

Mr. Groat. the time required for color to pass from one point in a system of conduits to another.

The temperature of samples is a very important matter in conductivity tests. However, if the method of special dilutions, or balanced samples, be adopted, the temperature correction will be eliminated.

In constructing the entrance to the outlet from the salt-solution tank, ample sectional area should be provided, else the full capacity of the tank may not be available, owing to the formation of vortices by reason of the high velocities generated. The outlet from the salt-solution tank in the present case was made of about 18 in. of 8-in. pipe, discharging vertically from the flat bottom of the tank into the 3-in. salt-solution supply pipe. In this manner, the water level in the tank can be drawn to the bottom without creating vortices or admitting air to the supply line.

For a number of years the writer has entertained the idea that a wire carrying an electric current could be used to measure the velocity of water. The current of electricity would tend to heat the wire, and the flow of water along and normal to the wire would tend to cool it, or to determine the temperature. The higher the velocity of the water, the lower the temperature of the wire. Therefore, the conductivity of the wire, or its temperature, would be a function of the velocity and, by having a calibrated apparatus for measuring the conductivity, or temperature, the velocity of the water could be determined. It does not appear, however, that much idea of direction of flow could be gained without getting into a very elaborate device. However, it may be well to mention the principle.

Referring again to the cost of turbine tests: This is a purely relative matter. Frequently, tests result in discoveries leading to improvements which pay for the tests many times over. In one case such improvements led to the recovery of a large amount of power at a cost of less than $1 per horse-power increase in capacity. The actual value of the gain was not less than $500 000, and the cost of the tests was only 1% of this value, an insignificant matter altogether. In another case, tests indicated simple changes in draft-chests, which effected a substantial increase in efficiency and power.

Attention has already been directed to the diagram of turbine performance, Plate LI. This diagram, it may be explained, gives all the information concerning turbine performance. It may be utilized to compile many kinds of tables which will be useful to designing and operating engineers and power-house superintendents. Such diagrams will be of great value in designing water-wheels to fit electric generators, and the converse. They will also be of great

value in making contracts and specifications for turbines, generators, and complete hydro-electric units. Mr. Groat.

The writer desires to express his appreciation and thanks to Messrs. Eimer and Amend for the chemical equipment used in illustration of the methods of chemi-hydrometry at the time of reading the paper of which this discussion is the conclusion. He also extends thanks to Mr. Hugh N. Davis, who very kindly assisted with the chemical operations on the same occasion.

The reader may have observed that Table 1 shows evidence of small systematic errors in the data from which it was compiled, especially for the weak concentrations. It may be well to bear this in mind when shrinkage becomes important, as a revision of Table 3 and Fig. 1 will doubtless be required when more correct data become available. This may also modify, or possibly negate, the thesis of Section 24, which states that a molecule of salt always displaces a portion of the water in which it is dissolved, however dilute the solution may be.

It may not be amiss to repeat that the writer considers Table 85, and the corresponding table of aggregates for Tests *N, O, P, Q, R* (Table 93), as showing the possibilities of current-meter work in turbulent water when the records are corrected by composite rating curves. The errors of 1 to 2% among the four methods for the individual tests are due to the fact that meters were not, in the case at hand, compared in one and the same test. The true precision attainable is apparent when all five of a group of tests are treated as a single test.

Paper No. 1367

ADDRESS AT THE ANNUAL CONVENTION, IN PITTSBURGH, PA., JUNE 27TH, 1916

By Clemens Herschel, President, Am. Soc. C. E.

As we approach the number in our order of exercises, which by Constitutional provision calls upon the President to deliver an Address at the Annual Convention, you no doubt feel, as I feel, that we stand in the shadow of the great loss this Society has suffered in the death of its duly elected President, Dr. Elmer Lawrence Corthell. Succeeding to his duties and responsibilities, I have endeavored to follow out any plans he may have had for the Address which he was to have delivered, but have been unable to learn that he left any definite written or oral memoranda with regard to it. "The night cometh when no man can work"; and it came to our late President, before he could communicate to others the thoughts he no doubt had with regard to this address, and had intended to incorporate in it.

It will not be foreign to his desires and aspirations, however, if I choose for the subject of our considerations, a topic that may well enlist the co-operation of us all; left to struggle with the world's work now that he is gone. Just 25 years ago, this your President was the newly elected President of the Boston Society of Civil Engineers; an engineering Society, let it be noted in passing, which was chartered in 1848, and which is thus the oldest organized engineering Society in the United States. At that time he chose for his subject: "The Advancement of the Profession of the Civil Engineer",*

* *Journal*, Assoc. of Eng. Societies, March, 1891.

and I have found it interesting to read what a younger man of the same name as myself (little else remains exactly the same between us), had to say on this subject 25 years ago. So much so, that I have ventured again to choose this subject, ever old, ever new, for your contemplation to-day.

We have had of late in the technical press and in the proceedings of engineering societies, ample evidence that the advancement of the profession of the civil engineer is a cause that still has the earnest attention of the large body of thoughtful working engineers of the country. The spirit of unrest has been abroad among them, and however much, content with one's individual lot may be ethically or religiously proper, and bringing blessings in its train, yet is unrest in behalf of one's class, and an altruistic, lawful striving to better the lot of that class, a commendable, and perhaps the only effective means of achieving that end, as experience has amply shown. Engineers feel that they occupy a prominent place in the creation of the world's material welfare, and want a recognition of this fact—a recognition that a share in the world's honors is due them, in the minds and actions of their fellow-men. Especially is their unrest and a striving for increased public recognition justifiable and prominent among engineers, when the creation of State or public works is under consideration.

Time was in this country, about 100 years ago, when it was denied that a State, or the United States, should undertake any, what were then called, "Internal Improvements"; what would now be called:—Public Works. We still suffer from that self-delusive attempt to ignore necessities that always have existed in countries reckoned civilized, or progressive; that always will exist. Wars and combats by land and sea, also in the air and underneath the sea, more than ever form mile-stones in the life of nations, as it is described in history; but the silent changes wrought by custom, and without bloody contest, in that same national life, are no less marked when viewed in a calm review of the centuries. What was natural and without material harm 100 years ago, has now become burdensome, and to thinking men, absurd.

Consider the state of society in this country in which could be passed a vote in town meeting (you may read it in the annals of a certain Connecticut Valley town), that "Cornelius the Irishman have

leave to take up land, but provided he have no voice in the town affairs"; and compare it with the state of affairs to-day in that same town, the stock derived from its original population submerged, even wholly extinguished, under the output of a "melting-pot", into which have been cast, at one time or another, specimens from all the nations of the earth; many of them of a most uncouth form and texture. Hardly less opposite is the need and propriety of public works to-day, as compared with that need and propriety in the young nation of 100 years ago, barely emerging from its colonial condition, and from a wilderness, apparently left on earth on purpose for it to subdue.

Says the poet:

"Bid the broad arch the dangerous flood contain,
The mole projected break the roaring main;
Back to his bounds their subject-sea command,
And roll obedient rivers through the land,—
These honors Peace to happy nations brings;
These are imperial arts, and worthy kings."

Public works have been deemed the glory of long-established, or developed, States, since the dawn of history. To attempt to do without them, or to rely solely upon private enterprise to procure them, is a mere delusion; or notion; impracticable; and yet we have a National, and, generally speaking, forty-eight State Governments, that make no permanent provision for their construction and up-keep, in their organic law.

The expenditure of 4% of the annual United States Budget on public works is made the foot-ball of politics, and great is the cry of victory when this expenditure has been reduced to 3½%; but no word is heard about the other 96 or 96½% of expenditure of the same budget; because public works are not recognized in the Constitutions of the United States and of the States, to the extent of providing a department of the Government, and permanent officers of the Government, to construct and care for them. A large part of the lack of recognition of the civil engineer as a member of an honorable profession, and of his merits, is, in my belief, traceable to this very state of affairs.

From time to time, the technical press contains discussions as to the anomalous position held by "Junior Engineers", and "Assistant Engineers" in the service of the United States, on public works, in

charge of the Corps of Engineers, U. S. Army; the former of whom can never rise above their basic position, and the best of whom consequently leave that kind of a service as quickly as circumstances will permit. These discussions are carried on in all sorts of tempers, and, to make my own temper clear in the matter, let me express the belief, founded on long personal observation and friendships, that there does not exist an abler, a finer body of men than this same Corps of Engineers, U. S. A. Think of its genesis. A boy must have ambition, must be a select boy, to aspire to go to West Point. Competitive examinations, in the majority of cases, cull out the best of these to go there. Four years' training and schooling, and their consequent process of selection, reduces the number who enter, to the half that is able to graduate. And of these, only the four or five at the head of the class go into the Corps of Engineers. Evidently the population of the United States cannot produce better men than these four or five, thus marked for high honors. The trouble is not there. It is because the whole system of carrying on the civil engineering works of the United States is an emergency makeshift; born of a denial of the propriety of the nation to build *any* civil engineering works, and of the *necessity* of building them, when their construction could no longer be avoided, by makeshift methods.

In one, perhaps the best, of these discussions,* that have just been referred to, is contained this closing argument:

"Will any one maintain that it [Congress] is yet prepared to commission men as Civil Engineers and give them a similar [to Army, Navy, Revenue Cutter, etc.] legal status?" And if we are to stop there, the argument is no doubt a sound one. So long as Congress is not "prepared" to commission Civil Engineers to do the civil engineering work of the United States Government, that work will have to be carried on as an emergency measure, and not as a regular function of government. But this is the day of "preparedness", and sooner or later, Congress also will have to become "prepared", in this, as in many other matters.

Says Laurence Sterne, in his "Sentimental Journey": "They order this matter better in France". And not only in France, but in every country of the globe, except in Great Britain, and in the United

* *Engineering News*, May 14th and June 11th, 1908.

States; the copyist of Great Britain, which the United States has been for so long, and in so many directions. The first named, all have a Ministry of Public Works, and, carrying on the business of this department, a corps of commissioned civil engineers. To that must the United States, and every State in the Union, come, sooner or later. Commissions of laymen to rule in these matters, appointed as an emergency measure, are an anomaly in these days of a striving for efficiency. See what says the President of the Institution of Civil Engineers, of Great Britain, James Charles Inglis, in his Annual Address for 1909. He quotes an economic authority to the effect that in the great struggle of the Twentieth Century it is in other countries the aim to leave as little as possible to chance; not to allow people to muddle through *somehow*, but to eliminate as far as possible the element of the unforeseen, while carefully training the mind to cope, in an intelligent way, with any emergency.

While the British had as a rule a violent suspicion of the expert, and a strong belief in the untrained, unpaid amateur as the bright source of wisdom, allowing the expert to advise and the amateur to decide, elsewhere there was no fear of the expert. There was indeed the possible danger of red tapeism at the hands of highly trained officials, but they would be found less than the dangers arising from the decisions of well-meaning but untrained and inexperienced amateurs;—all of which is applicable to the description of a contrast between the British and all the other European; between the United States method and a *rational* procedure in the construction and administration of public works.

Says President Inglis:

"If these principles were more acted upon in this country [Great Britain], as in time they must be, I think you will agree with me that many members of the Institution would find increased scope for their energies, and added interest in the engineering problems they have to deal with, while, without doubt, better results would, on the whole, ensue for capital."

Let me illustrate how the Commission habit in State Government operates; as philosophically viewed from a distance, in recent years. A certain State conceived the idea that it would be well to develop its principal seaport by works of the civil engineer. So a Commission of laymen was immediately created to cause this to be done. The

newspapers were replete for months as to who should be the Chairman of this Commission. There was a good salary attached. Not a word as to the Civil Engineer capable of designing the necessary works, and of wisely superintending the expenditure of millions of dollars in the future. Not one word. At length the die is cast, and the favorite of the "plum-tree" enters upon a course of the, at such times customary after-dinner speeches. After months of this sort of thing, and when the novelty of the situation has worn off, not much has been heard in the daily press as to the work to be done. An engineer has indeed been somehow appointed, and certain work planned and done. Then the former after-dinner speaker resigns, or is crowded out,—it is immaterial which,—changes of political government affect and *debase* the at-no-time illustrious commission and engineering corps, and the last end of that Commission is worse than its inception;—it is *itself* swallowed up and abolished in a reshuffling of the Commissions of the State generally; and all this in the space of barely 5 years; with the simultaneous hazard of millions of money to be expended, at once and in maintenance and repairs, or reconstruction in the future, in a foot-ball game of politics.

Is it not true, does one not see, in contemplating such bits of contemporaneous history, that especially in a Republic, are commissioned civil engineers needed for the proper carrying on of the public works of the State? The reason the average Congressman, even the Executive, respects the Army Engineer, as they do, is because the former knows that the services of the latter in and to the Government will go on, when he himself will not unlikely have been wholly forgotten. He would equally respect the commissioned civil engineer.

The layman Chief-of-Bureau's tendency to lack of consideration for his expert subordinate must be checked by the expert's permanence in the service, or else we can get no results in public works such as the State ought to have.

To illustrate again, where else than in the United States would it have been possible for a dreamer of patriotic visions, in the service of the Government, to have seen those visions come true under his able guidance in the space of some 15 years, and at an expenditure of scores of millions of dollars; creating empires of arable land, where before was the desert; and after the threat of political removal

by one brief layman incumbent of the chair at the head of his bureau, finally be made to succumb, without any justification that the public ever heard of, by another such brief incumbent, to the already manifested harm of the service, and of its future.

No amateur ruling the immediate present, of an important government work and agency, should have such subversive powers of harm for their future. No matter even that he act from motives which to him at the moment seem wholly good. He may be mistaken. Certain it is that a system that enables a mere passing temporarily exalted incumbent of an office thus radically to disorganize, out of his own mere motion, a work of national usefulness and importance, is not for the good of the body politic.

In a republic, with its short-lived, kaleidoscopic, ever-changing individual leadership form of government, even more than in a conservative monarchy, the servants of the State on public works, should have fixity of tenure of office. Verily, "they order this matter better in France"; a republic; and both better, and *by the same means* better, in many a country, besides France.

More could be said in the same line of argument and illustration, but the President's Address should not be tiresome, though the advancement of the Profession of the Civil Engineer can be viewed from many another angle. Indeed, in contemplating it, one is reminded of the lament of the New England conscience,—no one felt it more than he whom inadequately I am trying to replace to you,—"so much to do; so little done".

We have, for instance, the work of combining the efforts of the various branches of the Engineering Profession, in matters of their common interest. According to Section 2 of Article II of our Constitution, there are no engineers, except civil and military engineers; the original class distinction. But so various are to-day the occasions when it is necessary to apply "the art of directing the great sources of power in Nature for the use and convenience of man", that it long ago became impracticable to have all engineers in the United States enrolled in one American Society of Civil Engineers. Instead, we have the four prominent National Engineering Societies, and many amply useful, though less prominent, such engineering Societies. And yet the number of their aggregate membership is small, compared with

the population which they serve; a prominent reason why their expressed desires are too often but as a "voice crying in the wilderness". To remedy this condition which confronts us, many have labored, in season, and out of season, to bring about joint action of the engineers of the United States in matters of a common interest. This Society has said that it believes in it, and as a step in that direction, as facilitating that sort of work, as a landmark and a beacon light to the public, that engineers are at their posts of duty and should be recognized and reckoned with, we have said that the building of the four Founder Engineering Societies on 39th Street in the City of New York shall represent to the public, the home of a power in the land. The step we have taken and which has been voted in the affirmative, 2 500 for, 390 against, is of course but a beginning. It has been worked for in a duly humble spirit, and on the principle of doing one thing at a time, but the beneficent end of that work no man can see. "Be of good comfort, Master Ridley," Latimer cried at the crackling of the flames, "play the man! We shall this day light such a candle, by God's grace, as I trust shall never be put out." Not only not put out, but increasing through the years, in effulgence, glory to the profession, and in usefulness.

I have said that the advancement of the Profession of the Civil Engineer in the United States, could be viewed from many another angle. This has nigh exhaustively been done by one of our distinguished fellow-members in a paper read February 29th, 1916, in this very city.*

There is the education of the engineer properly to be attended to. Is he, while thus in embryo, doing 24 hours of work and refreshment, in the 24 hours of the day? Is the work he is doing of the right kind?

We have many able fellow-members who are giving the travail of their lives to answer these questions.

There is reform within the active profession to be attended to. Is the typewriter machine and printing press already working overtime; running away with the drafting table and with service on the work and in the field, and with learning from Nature by experiment? What constitutes a legitimate consulting engineer? Not in the eyes of the great discerning public, but rather in those of his professional brethren.

* To be, or already published, by the Engineers' Society of Western Pennsylvania: a paper by J. A. L. Waddell, M. Am. Soc. C. E., of Kansas City, Mo.

Legislation in forty-eight States of the Union and in the Congress of the United States must be taken note of, to prevent harmful enactments, and to support those we know to be good for the body politic, no less than for the Profession of the Civil Engineer.

Not as a lamentation or a sigh of weariness, but as a cry and a call to additional, and to continued service to our profession and to mankind, let us say: As yet, *"So little done"*.

Paper No. 1368

COHESION IN EARTH: THE NEED FOR COMPREHENSIVE EXPERIMENTATION TO DETERMINE THE COEFFICIENTS OF COHESION*

By William Cain, M. Am. Soc. C. E.

With Discussion by Messrs. Clifford Richardson, F. W. Green, E. P. Goodrich, and William Cain.

Synopsis.

The ordinary theory of earth pressure pertains to a granular material, such as clean sand, gravel, or rip-rap, supposed to be endowed with friction only. For ordinary earth, and particularly with clay, experiments given show that, in addition to friction, the earth is endowed with cohesion, and the practical importance of determining experimentally the simultaneous coefficients of friction and cohesion for every variety of earth is earnestly urged.

The results of the few experiments made on various earths and clays are given, and attention is called to the small values of the coefficients of friction and to the large values of the coefficients of cohesion in the case of consolidated earth and clay.

Harking back to the laws of friction and cohesion, first formulated by Coulomb, a simple form of apparatus for experimenting is given to illustrate principles, though it is realized that, when the earth is subjected to great pressures, a more complete testing machine is

* Presented at the meeting of February 2d, 1916.

desirable. In fact, a standard machine to which engineers could send samples of earth to be tested, seems desirable.

The results of the more recent experiments made, in both France and England, are, in some respects, so unexpected and significant that a mere glance at the figures will show the immediate need of a comprehensive system of experimenting, not only to determine the true laws of friction and cohesion of earth, but likewise to determine the coefficients of friction and cohesion for ordinary earths and clay, in various stages of consolidation.

Coulomb, about 1780, was the first to formulate the laws of friction and cohesion, as affecting a mass of earth. For a homogeneous earth, these laws may be stated thus:

(1) The maximum frictional resistance that can be exerted along any portion of a plane in the interior of a mass of earth equals the normal pressure, P_n, on the portion of the plane considered, multiplied by f, the coefficient of friction, where f is a constant for the earth considered.

(2) The maximum cohesion equals the area of the portion of the plane considered, multiplied by k, the coefficient of cohesion, or cohesion per unit of area, where k is a constant for the particular earth in question. Thus, if A denotes the area of the portion of the plane under compression and Q the total resistance to sliding along this interior plane, then,

$$Q = P_n f + k A \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

A great number of experiments have been made to determine f, the coefficient of friction for various materials, on the supposition that k was either zero or negligible; but very few have been made to determine, at the same time, the coefficients of cohesion.

A limited number of experiments, with this object in view, have been made by Collin (1846), Leygue (1885), Jacquinot and Frontard (1910), and A. L. Bell (1914). With the exception of Collin, the experimenters determined the coefficients, f and k, from the same set of experiments. Although the apparatus used by one experimenter was not the same as that used by any other, yet, in principle, the following simple device can be supposed to represent the method of

experimenting. In Fig. 1, a thin slice of earth is supposed to be placed between two metallic plaques, which are rough on the inside. These are then firmly pressed together, but without contact, and the resistance to the relative displacement of the two plaques is then measured.

Suppose the pressure to be due to a weight, and let P_n represent the sum of this weight and that of the earth and plaque above the horizontal plane of shear, AB; also, let Q be such a horizontal force applied (through a cord) to the upper plaque in the plane, AB, that sliding of the earth above the plane, AB, over the earth below it is "impending", which means that the slightest increase in Q would cause actual sliding. The earth along the plane, AB, of the area, A, resists the force, Q, by the friction and cohesion acting to the left along AB; hence, for equilibrium, at the instant motion is impending, we have,

$$Q = f\,P_n + k\,A.$$

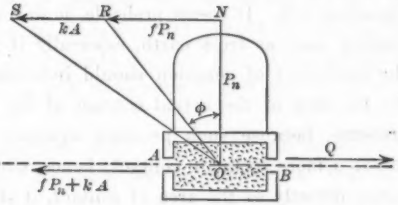

FIG. 1.

The normal reaction of the earth just below the plane, AB, $= P_n$; hence, if $ON = P_n$ is laid off vertically upward, and $NR = f\,P_n$ and $RS = k\,A$ are drawn horizontally to the left, then $NS = f\,P_n + k\,A = Q$. Also, if ϕ denotes the "angle of friction" of the earth, then $f = \tan.\,\phi$; so that the angle $NOR = \phi$. Note carefully that, in earth endowed with both friction and cohesion—coherent earth, as it may be styled—the "angle of friction" is not the surface "angle of repose." The latter is always greater than ϕ, a definite mathematical relation existing between the two angles and the depth of embankment.

If we designate by p_n the normal pressure per square foot on the plane, AB, and by q the total resistance to sliding per square foot of the plane, then, by dividing both sides of the preceding equation by A, we obtain,

$$q = f\,p_n + k = p_n \tan.\,\phi + k \ldots\ldots\ldots\ldots\ldots (2)$$

where q, p_n, and k will be expressed in tons, or pounds per square foot, according as Q and P_n are expressed in tons or pounds. As k and $\tan.\,\phi$, for any particular homogeneous earth, are constants, if the variable normal unit pressure, p_n, is laid off, from the origin, along

the axis of abscissas, then the corresponding value of q can be represented by an ordinate, and the equation is that of a straight line, making the angle, ϕ, with the axis of abscissas and cutting the axis of ordinates at the distance, k, above the origin. From the results of the experiments, simultaneous values of p_n and q can be plotted, and an average line drawn; otherwise, corresponding experimental values of p_n and q can be substituted in an equation of the foregoing type, and, from the resulting equations, the most probable values of tan. ϕ and k can be found by the method of least squares.

It may be said that it is still an open question, whether friction and cohesion, according to Laws (1) and (2), are both exerted at the same time, but the limited number of experiments which have been made seem to justify the assumptions and to verify approximately Equation (2). It seems probable, however, for very compressible substances, such as fresh earth, especially if pulverized or in lumps, that the coefficient of cohesion should increase with the normal pressure; for the area of the actual contact of the particles increases with the pressure, because such pressure squeezes the particles together and causes a more intimate contact; hence, since, by Law (2), the cohesion varies directly as the area of contact, it should prove, for such earths, the greater the larger the normal pressure.

This objection applies to a much less degree to a slice of earth cut out of a bank and experimented on in its virgin state, just as it was in the bank. However, if fresh, clayey earth is taken from a new embankment, the earth being more or less pulverized, the coefficient of cohesion is doubtless small; but if such earth is thoroughly wetted and rammed, so as to approximate to a puddle wall, its cohesion is very much increased, as the contact of the particles is more intimate than when the earth was in a friable state.

From similar considerations, it would appear reasonable to suppose that the unit cohesion in a bank of earth should increase with its depth, so that it is highly desirable to subject the earth, between the plaques, to pressures corresponding with those actually sustained in banks, say, up to 50 ft., or more, in height, in order to ascertain the variation, if any, in the coefficient of cohesion. If this variation with the height is appreciable, then an average value of the coefficient, for a particular height of bank, will have to be assumed for the imaginary

homogeneous earth to which the theory pertaining to coherent earth strictly applies.

It may be remarked, further, that Equations (1) and (2) are only valid when no relative motion of the plaques occurs. When motion once occurs, it would seem that the cohesion of the earth along AB would be destroyed, and that only friction is exerted. This is analogous to the case of the trench, in which constructors are very solicitous about placing the bracing before a break in the earth starts, for in such case, the cohesion along the surface of the earth is lost, only friction remaining, so that the pressure on the bracing is very much increased. If this reasoning is true, is not the "friction of motion" between any two bodies (wood, iron, stone, etc.), more nearly the true friction than the "friction at rest"? It is possible that cohesion as well as friction may be exerted between any two bodies at rest, so that expressions of the form of Equation (1) should be written to correspond to the results of experiments made as previously indicated. The solution of such equations will determine f, and also k, if it is not zero, as usually assumed.

The results of the experiments on earth to determine the coefficients, $f = \tan. \phi$ and k, after a method equivalent in principle to that just outlined will now be given.

In the experiments of Leygue,* the normal pressures were very small—only from 7 to 40 lb. per sq. ft.—but the laws of Coulomb were practically verified within these narrow limits. The results were:

Dry sand.....	$f = 0.70$	$\phi = 35°$	$k =$ 1.47 lb. per sq. ft.
Wet sand.....	$f = 0.85$	$\phi = 40° 22'$	$k =$ 8.28 " " " "
Very wet sand.....	$f = 1.70$	$\phi = 59° 30'$	$k =$ 6.36 " " " "
Damp fresh earth...	$f = 1.63$	$\phi = 58° 28'$	$k =$ 18.45 " " " "

Leygue states that Collin found, by an independent method, that for clayey earth, $k = 23.1$; and that for clay of little consistency, $k = 39.5$ lb. per sq. ft.

From the small value for cohesion for dry sand (only 1.47 lb. per sq. ft.), Leygue seemed to be warranted in ignoring it in analyzing the results of his carefully conducted experiments on retaining walls and boards. As the results did not agree very well with those of the

* "Nouvelle Recherche sur la Poussée des Terres," *Annales des Ponts et Chaussées*, 1885, Part II, p. 788.

sliding-wedge theory, ignoring cohesion, the writer reviewed the subject of experimental walls in an extended paper,* reaching the following results:

For walls a few feet in height, backed by dry sand, the ordinary sliding-wedge theory, ignoring cohesion, agreed in its results fairly well with those of experiments, provided the friction between the earth and wall was included from the start; but that the Rankine theory was not sustained generally by the experiments. In Leygue's experiments, however, the walls or boards were only a few inches in height, and it was found that the influence of cohesion was marked and that the results could only be harmonized with theory by including the influence of cohesion as well as that of friction. The cohesion required was very small—only about 1 lb. per sq. ft., which is a little less than that found by direct experiment—but its influence on the results was marked, owing to the small height and consequent small weight of the prism or wedge of rupture. In the course of the investigation, a complete graphical method was devised, which can be applied in ascertaining the thrusts against retaining walls and trench bracing for the coherent earth supposed. In such applications, it is absolutely necessary to find the coefficients, f and k, by the method previously detailed. In fact, the value of ϕ for consolidated earth is found to be much less than the usual so-called "angle of repose", and its low experimental value, as given in the remaining results, will doubtless give a decided shock to those not familiar with this recent experimenting.

The results of the experiments made in 1910, by MM. Jacquinot and Frontard,† on earth taken from an earthen reservoir dam which had failed owing to a considerable lowering of the water level, will next be given. The dam was constructed in the most approved manner, of the best materials, the composition of the earth tested being 60% clay, 32% silica, as an impalpable dust, and 8% silicious sand. Water was added to the earth, and it was then kneaded and compressed with the hands so as to make a firm though pasty cake, which was then inserted between the plaques. Not enough water was added to cause a lateral flow when the cake was under compression. The details of

* "Experiments on Retaining Walls and Pressures on Tunnels", *Transactions*, Am. Soc. C. E., Vol. LXXII (1911), p. 403.

† Given in some detail by Professor Résal in his work, "Poussée des Terres", Part II, "Theorie des Terres Coherentes", p. 327, Paris, 1910.

the apparatus used are not given. The results for the first series of experiments are given in Table 1.

TABLE 1.

p_n, in pounds per square foot.	$f = \tan. \phi.$ $\phi = 8°.$	k, in pounds per square foot.
692	$f = 0.14$	395
2 980	$f = 0.14$	420
5 665	$f = 0.14$	403
7 154	$f = 0.14$	448

The earth in the bank weighed 112 lb. per cu. ft., so that the recorded pressures corresponded to the vertical pressures experienced at depths of from 6 to 64 ft. for the earth in question.

After the first series of experiments had been performed, the manometers got out of order, so that a correction had to be applied, and, as there was some doubt as to the accuracy of the results, they will not be given. From all the experiments, however, some referring to the earth as it was taken out of the bank, and some to rammed earth, the quantity of water being varied, it seemed that the following conclusions, as stated essentially by Résal, could fairly be drawn:

(1) Coulomb's laws were approximately verified.

(2) $f = \tan. \phi$ ranged only from 0.14 for a soft pasty earth to 0.18 for the earth nearly dry. Neither the quantity of water used, nor the ramming or puddling, caused much variation in f.

(3) On the other hand, the quantity of water used affected the cohesion very much, and sufficient ramming could more than double the coefficient of cohesion.

The large values of k were to be anticipated, as the theory of open cuts and trenches would lead one to expect, for ordinary consolidated earth, values of k running into several hundred pounds, but the low values of ϕ (only from 8 to 10°) are somewhat startling, and indicate that our ideas with respect to the coefficient, f, and earth-pressure theory generally, may have to be considerably revised.

The values of k and ϕ, given in Table 2, lead to the same conclusions. They represent the results of experiments on clay, in its virgin state, as taken at various depths from an excavation carried

below low water, in the course of sinking a large number of monoliths which are to form the foundation of the outer sea-wall of a dockyard at Rosyth.*

The figures given represent fair average values for k and ϕ.

TABLE 2.

	k, in tons per square foot.	ϕ, in degrees.
Very soft puddle clay	0.2	0
Soft puddle clay	0.3	3
Moderately firm clay	0.5	5
Stiff clay	0.7	7
Very stiff boulder clay	1.6	16

By the term, "puddle clay", is meant a pure, homogeneous, plastic clay, free from sand or stones. As to the time element, it is stated that all the tests were of considerable duration.

In the discussion of the paper, Dr. Unwin called attention to the important fact that Collin, in 1846, found that the resistance to shear in clay produced in 12 or 15 min. was only one-third or one-fourth of that produced in 12 to 15 sec. Mr. Bell stated that experiments were made also on perfectly dry sand, for which it was found that practically $k = 0$, and that the results were in agreement with the equation, $q = f\,p_n = \tan.\ \phi\ p_n$, where, in this case, ϕ was the "angle of repose", provided the sand was rammed in the cylinder of the testing apparatus; but if it was merely poured in and shaken, then it was found that the angle, ϕ, of the equation was much less than the angle of repose.

Enough has been given to show the absolute need of a series of comprehensive tests to determine the coefficients, f and k, for every class of material. It is highly desirable, too, to have a permanent testing laboratory, with an apparatus capable of subjecting the earth to pressures varying from 0 to at least 10 tons per sq. ft., to which earth could be sent from any locality to have its coefficients, f and k, ascertained.

* The experiments were made under the direction of Mr. A. L. Bell, the results being published in *Minutes of Proceedings*, Inst. C. E., Vol. CXCIX, Session 1914–15, Part I, in a paper by Mr. Bell entitled "The Lateral Pressure and Resistance of Clay and the Supporting Power of Clay Foundations."

In designing the apparatus for testing the earth, it will be unfortunate if certain objectionable features of some previous designs are repeated. Thus, in Leygue's peculiar apparatus, a certain portion of the weight of earth and load was held up by the vertical sides of the box by friction, for which allowance had to be made. No error from this cause attaches to the very simple design shown in Fig. 1, where there is only contact of earth on earth and no contact of metal on metal. Likewise, in testing, although the effect of ramming and puddling should not be neglected, it seems reasonable to suppose that the most correct determinations of f and k could be obtained from the earth cut out of the bank or in its virgin state, especially when subjected to the pressure it bore in the bank. Then, too, careful experiments should be made to determine the effect of the time element, particularly for a substance like clay.

It seems needless to point out the practical importance of such experimenting, for it has long been recognized that, although certain theories of earth pressure give fairly correct results when the filling consists of a strictly granular material, such as sand, gravel, or rip-rap, yet when such filling consists of ordinary earth, endowed with cohesion, it is found that the theory is inadequate or, strictly speaking, that it is inapplicable, and that the theory for coherent earth must be applied.

Take, for example, the earth in the embankment or reservoir dam which failed, as previously cited. Possibly the fresh earth had a natural slope of 1 on 1½, before it was rolled, etc., and if placed behind a retaining wall, the thrust would have been computed (for $\phi = 33° 41'$) for an earth devoid of cohesion, on the supposition that the thrust thus found was in excess and, therefore, on the side of safety.

Suppose, however, that this filling was laid in horizontal layers and wetted and rolled or tamped, so that, as already found, the "angle of friction" (not the maximum inclination of the surface possible) was only 8° and k was 400 lb. per sq. ft.; then, perforce, the theory of coherent earth would have to be applied in order to obtain the true thrust. For a similar illustration, take the retaining walls designed by Gustav Lindenthal, M. Am. Soc. C. E., for a concrete viaduct 65 ft. high. These walls were thin and vertical, were placed on each side of the roadway, and were connected by tie-rods, the space between being filled with earth thoroughly tamped and consolidated.* In this

* *Engineering News*, May 6th, 1915.

case, the earth thrust can only be guessed at, unless the coefficients, f and k, are determined by experiment, in which case the theory of coherent earth will give the exact thrust. In fact, it is seen that Equation (1) exactly applies in finding the resistance to sliding along the plane of rupture.

Again, Mr. Bell's experiments, already cited, were made with the express purpose, not only of finding the earth thrust from the material surrounding the monoliths, but likewise the permissible pressures to which the clay under the monoliths could be subjected. The latter involved the theory of a possible heaving of the wall at the heel from the earth pressure behind it, or a possible heaving of the earth in front of the wall from the pressure of the latter at its toe. For the foundation, it was assumed, for the stiff boulder clay encountered, that $k = 1.5$ tons per sq. ft. and $\phi = 15$ degrees. The results would have been absurd, if k had been assumed equal to zero, as in the ordinary theory. In fact, this ordinary theory (for $k = 0$) is rarely ever applicable to foundations, which almost invariably are in consolidated earth or clay having a high coefficient of cohesion.

In addition to the subjects previously mentioned, may be cited the earth pressure on the bracing of trenches, the pressures on tunnel linings, and on piling, and the stability of slopes, none of which can be properly treated without experimental determinations of the coefficients, f and k, for the material encountered.

The theory of pressures in coherent earth is at hand—at least for homogeneous earth—but it cannot be applied without a more extended knowledge of the coefficients, f and k. In some of the recent texts, there has been a tendency to pull down existing theory. One aim of this paper is to encourage the building up of a better and more comprehensive theory—one which deals with coherent earth for the general case, and reduces to the ordinary theory for materials nearly devoid of cohesion, such as sand, gravel, or rip-rap. Such a general theory introduces all the vital elements which are necessary for a solution.

It is fully realized that changes may occur in the values of f and k from weathering, vibrations, freezing and thawing, rains, and chemical changes, so that a prudent engineer will anticipate and allow for such changes; but this, again, only emphasizes the need of experiments on a particular earth covering a long period of years.

The term, "angle of internal friction", has been introduced into engineering literature in recent years, causing much confusion and mental perplexity; for, since for dry sand, the law, $q = f\ p_n$, practically holds, then, $f = \tan.\ \phi$ is the same for the interior as for the surface, and ϕ is then truly the ordinary "angle of repose". For a homogeneous, coherent earth, however, $q = f\ p_n + k$, where k and $f = \tan.\ \phi$ are constants, though now, ϕ no longer represents the possible maximum surface inclination, but the "angle of friction", as found from experiment, after the manner previously indicated. Thus, there should be no possible confusion of terms in introducing this new (old) theory.

The subject has been brought up at this time because the Society, through one of its Special Committees, is now engaged in a general investigation of the bearing value of soils, earth pressures, etc., and, in the writer's opinion, the most hopeful method of attack is along the lines indicated herein.

DISCUSSION

Mr. Richardson.

CLIFFORD RICHARDSON,* M. AM. SOC. C. E. (by letter).—The writer has examined this paper with some interest, and requests the author to define "cohesion" in the sense that the word is used therein. Does this term denote "the state in which, or the force by which, the molecules of the same material are bound together, so as to form a continuous homogeneous mass", as defined by the Century Dictionary? or is it used to denote merely the sticking together of particles by natural attraction, without, necessarily, involving the entire homogeneity of the material, in which case the question of surfaces and films is involved? It is the writer's idea that the stability of earth and soil is more satisfactorily explained by considering them as a mixture of fine particles possessing a large area of surface to which water may or does adhere, forming a system of two phases which should be studied from the point of view of modern physical chemistry. With an increase of fineness of any material, the surface areas of these particles likewise increase to an enormous extent, and this has very great influence over its physical character.

The writer has shown† that the surface area represented by 1 gramme of sand of uniform size increases from 15 sq. cm. for a material which will pass a 10-mesh sieve up to 9 056 sq. cm. for material so fine that it does not settle out of water after agitation in less than 16 hours. The data to which reference is made are as follows:

"ONE GRAM OF SAND OF UNIFORM SIZE CONTAINS

"Mesh Sieve.	Millimeter.	Particles.	Square Centimeters.
10	1.50	212.8	15.0
20	.84	1 215.9	27.0
30	.58	3 693.6	39.4
40	.40	11 261.0	56.6
50	.26	41 005.0	87.1
80	.20	90 066.0	113.2
100	.13	328 032.0	174.2
200	.08	1 407 620.0	283.0
1 minute	.05	5 648 700.0	442.4
30 minutes	.025	46 124 900.0	905.7
2 hours	.0075	6 800 990 000.0	1 201.6
16 hours	.0025	46 124 900 000.0	9 056.6"

It will be seen, therefore, that the stability of any earth fill depends on the size of the particles and the area which their surfaces present, when considered in relation to a liquid phase, water.

It will be of interest, in connection with this subject, to study the principles of the modern chemistry of colloids which relate to surfaces

* New York City.

† In his book "The Modern Asphalt Pavement", 2d ed., p. 358.

and films.* These principles have a large bearing on the subject treated in this paper. Mr. Richardson.

F. W. GREEN,† ASSOC. M. AM. SOC. C. E. (by letter).—A rational and satisfactory theory of earth pressure has never been developed. For many years, the designer has had to content himself with an adherence to the theories of Rankine, Coulomb, Weyrauch, and others, based on various assumptions necessary to simplify the mathematical treatment, or to place his reliance on the empirical rules proposed by Sir Benjamin Baker, Trautwine, and others; and then to modify the conclusions thus obtained, in any case, by making certain arbitrary concessions to his experience and judgment. A conscientious engineer deplores such a necessity, which requires him to take chances between stability on the one hand and economy on the other. The author's effort to illuminate this subject in his paper is most interesting and praiseworthy. Mr. Green.

In the Century Dictionary cohesion is defined as follows:

"* * * the state in which, or the force by which, the molecules of the same material are bound together, so as to form a continuous, homogeneous mass. This force acts sensibly at insensible distances—that is, when the particles of matter which it unites are placed in apparent contact. At insensible distances it is a much greater, at sensible distances a much smaller force than gravitation, so that it does not follow the law of variation of the latter. It unites the particles of a homogeneous body, and is thus distinguished from *adhesion*, which takes place between the molecules of different masses or substances, as between fluids and solids, and from *chemical attraction*, which unites the atoms of a molecule together. The power of cohesion in a body is estimated by the force necessary to pull its parts asunder. In general, cohesion is most powerful among the particles of solid bodies, weaker among those of liquids, and least of all, or entirely wanting, in elastic fluids, as air and gases. Hardness, softness, tenacity, elasticity, malleability, ductility, and in crystallized bodies, cleavage, are to be considered properties dependent upon cohesion. The most powerful influence which tends to diminish cohesion is heat, as shown in the change of a solid to a liquid, or of a liquid to a gas, which is effected by it."

In all cases in actual practice, it may be said with confidence that the material to be held by a retaining wall is not homogeneous in the scientific sense. It may be all earth, but it is very doubtful, indeed, if it will ever be strictly homogeneous earth; and, if not homogeneous, it cannot be acted on by the force of cohesion. In the writer's opinion, therefore, the apparatus shown in Fig. 1 cannot measure cohesion. The ratio of Q to P_n is the coefficient of static friction of the material tested.

* Outlined in a most satisfactory manner in a book entitled "The Chemistry of Colloids and Some Technical Applications", by W. W. Taylor.

† Stamps, Ark.

Mr. Green. It is well known that the coefficient of friction is highly variable. In the Galton-Westinghouse tests, it was found that its value varied from 0.074 at 60 miles per hour to about 0.340 static, using cast-iron brake-shoes on steel tires. Static friction itself is far from being a constant quantity, moisture and temperature greatly affecting it. Rankine* gives for clay, from damp to wet, values for f varying between 1.00 for the former to 0.25 for the latter. In the writer's own experience, he has encountered an alluvial silt which, after thorough saturation, took a slope of 7:1, or a value for f of 0.143. May we not with propriety conclude, therefore, that the failure of so many retaining walls is chargeable to the use, by the designer, of a coefficient of friction which, in theory, is based on a dry granular material, but, in fact, on a wet, slippery material, rather than to a failure to introduce a cohesion factor into his computations? In other words, if proper consideration is given to the phenomenon of a variable adhesion, will the problem not resolve itself into the same thing as a constant coefficient of friction (which is the measure of the constant adhesion) plus a so-called cohesion factor (which, in reality, indicates the upper and lower limits between which variable adhesion fluctuates)? If the wall is designed for the worst anticipated conditions, as to nature of back-filling, drainage, frost, etc., instead of for "a dry granular mass without cohesion, etc.", it should not fail if properly constructed.

Cohesion is stated by many writers as being the force which prevents the sides of newly excavated trenches from caving in, and the material taking the natural slope. In the writer's opinion, which is admittedly iconoclastic, this is nothing more than another illustration of the variable nature of adhesion. The material before excavation is thoroughly compacted, that is, the particles are in especially intimate contact, so intimate, in fact, that the force of gravitation cannot at once unbalance the interior forces and thus produce movement. Eventually, moisture evaporates, atmospheric pressure enters, and then gravitation wins.

Mr. Goodrich. E. P. GOODRICH,† M. AM. SOC. C. E.—The speaker desires to commend the author for his plea for clearer thinking and for more careful analysis of physical phenomena connected with earth pressures, but does not believe that the point raised with reference to internal friction is of material moment, even though there may be theoretical reasons which lead to a possible division into sliding friction proper and cohesion. The author points out that unit cohesion will probably be found to increase with depth, and is, therefore, variable. In his discussion of the element of friction, he also suggests that a variation may occur. Should it be found that

* "Civil Engineering", p. 316.

† New York City.

Mr. Goodrich.

these two elements vary according to different laws, it may conduce to clarity of thought to analyze them separately; but should the laws of variation be found to be practically identical, or the amount of variation in one case or the other very slight, then there appears to be no practical reason for not using a single element to include both factors and including both in a common term. For the sake of clarity, the term "angle of internal friction" seems to the speaker to be as good as any.

It is not understood that the author objects to the internal friction theory as applied to many other materials, as it would seem impossible that such could be the case on the part of any one who has studied with care the analysis made by Professor Basquin in a paper* before the Western Society of Engineers in 1912. The fact that results of such marked concordance can be secured when computed by the theory of internal friction (ignoring cohesion), in comparison with tests, leads to the conclusion that the separation, suggested by the author, between sliding friction and cohesion is probably unnecessary. Table 4, which illustrates this concordance of results, has been computed by Professor Basquin.

TABLE 4—ANGLE OF RUPTURE.

Material.	ANGLE.	
	Observed.	Computed.
Cast iron, Specimen *A*	54.8°	55.3°
" " " *B*	55	53.4
Limestone	62.2	61.7
Asphalt paving brick	59.7	58.6
Milwaukee brick	58.2	58.5

The diagrams in Professor Basquin's paper, with reference to the principal stresses developed in thick cylinders, according to the theories of internal friction, maximum principal stress, maximum principal strain, and maximum shearing stress, show such a striking concordance with fact in the case of the results computed by the theory of internal friction (ignoring cohesion), that the author's suggestion would seem to be of small weight. Finally, Professor Basquin's use of the diagram of circular stress in analyzing one of the experiments on bank sand, reported in the speaker's paper on "Lateral Earth Pressures and Related Phenomena",† discloses the relative importance of cohesion and sliding friction in the case of that earth, and with a uniformity of result which is believed to go far toward demonstrating

* "The Circular Diagram of Stress and Its Application to the Theory of Internal Friction", *Journal*, Western Soc. of Engrs., Vol. XVII, p. 815.

† *Transactions*, Am. Soc. C. E., Vol. LIII, p. 272.

Mr. Goodrich.

the fact that internal friction is the largest factor in earth pressure phenomena, and that a knowledge with regard to this will make possible a fairly accurate analysis of earth pressures.

The speaker heartily agrees with the author's suggestion that the Special Committee of the Society which is making investigations of earth pressure matters should have placed at its disposal a properly equipped laboratory, if it is to do any work of value.

It is not understood that a recommendation is made as to any special testing scheme, the special device suggested by the author having been found, more than 12 years ago, to be inadequate to secure accurate results, the speaker turning finally to his testing cylinder, because it provided results which were not approached, with regard to consistency and sensitiveness, by any other device. The results of these tests with the sliding boxes, in experiments on clay, were found to be extremely difficult of interpretation. Plastic clay is almost viscous in its action, so that motion of the boxes commenced under very small stresses and actually attained a visible velocity with increases of load, even before the one at which a proper break occurred and sliding friction was developed.

Difficulties of other kinds were also encountered in the use of the boxes, which were not susceptible of being overcome by the speaker. The sensitiveness necessary in any apparatus is illustrated by the fact that his early experiments were made with cigar boxes filled with sand, and the angle of friction was measured by tilting the boxes until one slid over the other. It was found that when the first two boxes used (which were, respectively, 3 and 5 in. deep) were reversed in position, the angle of tilt at which sliding took place differed. Such a sensitiveness to load conditions was susceptible of careful determination only with accurate testing machinery, and, in consequence, the cylinder was developed. In the early experiments with the latter device, it was found that infinitesimal displacements of the soil particles produced marked changes in internal stresses.

It was thus proved indispensable that some device should be invented which would maintain internal stress and strain conditions with practical exactness. The electrical device finally installed made this possible, and it is interesting to note that the Government, in its testing experiments, has not yet been able to improve the speaker's type of design of apparatus so as to increase its sensitiveness materially. Earth is elastic to a certain extent, and as long as the strains are within this very minute elastic limit (the existence of which experiments have demonstrated), it is probable that stress changes, which are materially different from those in the earth mass in its virgin state, do not take place. The analysis of the work done by the speaker is believed to demonstrate that the experiments with

the cylinder, when analyzed by means of Rankine's formula, will give the angles of internal friction (using the word in the sense deprecated by the author), and that a series of such tests under varying pressures, when plotted in accordance with the scheme developed by Professor Basquin, will give what the author desires, *viz.*, both sliding friction and cohesion. Mr. Goodrich.

In passing, it is interesting to note that the author, in his very interesting paper on "Stresses in Wedge-shaped Reinforced Concrete Beams",* used the very term, "internal friction", which he condemns in this paper. He should doubtless be forgiven, because each has the privilege of changing his mind, but it seems to the speaker that the expression is both appropriate and descriptive, and that it will hardly be surrendered, because of a more or less theoretical idea that the internal phenomena combine two variables. The speaker wishes to repeat most emphatically his statement of belief that it is absolutely necessary to secure a vast amount of adequate information in regard to soils of all kinds. To this end it is hoped that the Special Committee of the Society will be given every opportunity to make extensive and exhaustive experiments.

WILLIAM CAIN,† M. AM. SOC. C. E. (by letter).—Both Mr. Richardson and Mr. Green refer to the definition of cohesion as given in the Century Dictionary. This definition appeals perhaps more to some physicists than to the engineer. The writer has always had in mind the following definition, as given in the Standard Dictionary: Mr. Cain.

"Cohesion is that force by which molecules of the same kind or of the same body are held together, so that the body resists being pulled to pieces. * * *

"The distinction between *cohesion* and *adhesion*, once insisted upon strongly, is not now generally regarded as fundamental. Some physicists have limited *cohesion* to particles of the same kind, others to those of the same body. Thus the force that holds the mica to the feldspar in granite would be called *cohesion* by some, and *adhesion* by others."

As is evident from this definition and the accompanying comments, the word "body" can refer to a heterogeneous mass, as a mass of earth, or a granite rock consisting of quartz, feldspar, and mica, and it is plain that there is authority—even among physicists—for the statement that any heterogeneous mass of earth may be endowed with cohesion.

Certainly, as far as the writer knows, engineers have always held this view, evidently for the reason that they are principally concerned with the resistance to sliding of the earth along a plane, and, to a limited extent, to its tensile resistance, the word "earth" referring

* *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 745.
† Chapel Hill, N. C.

Mr. Cain. to clay or to any heterogeneous mixture of sand or gravel with clay or clayey matter, and perhaps humus, with more or less moisture. At one extreme, we may have nearly clean, dry sand with very little cohesion; at the other extreme, pure clay with a large cohesive resistance. In fact, clay and consolidated earth act like a solid in being able to resist both tensile and shearing forces; but they differ from a solid (as iron) in this, that their elasticity is null or imperfect, and their properties vary very greatly with the heat and moisture present, with the consequent freezing and thawing, and the chemical changes that may occur. The properties of earth are likewise affected by vibration due to heavy moving trains or vehicles, so that, in consequence of the various influences cited, the time element comes in, which thus differentiates it from a solid, such as steel when properly protected from chemical changes.

The term "cohesive resistance" of earth may properly apply either to its tensile resistance or to its resistance to sliding along a plane in the earth, dependent on the viewpoint. However, as the tensile resistance of the earth is rarely called for, the term "cohesive resistance of earth", from Coulomb's time to the present, has been generally restricted to mean the resistance to sliding as affected by cohesion, exactly as given by Coulomb's two laws and the resulting Equations (1) and (2), referring to Fig. 1.

As previously stated, these two laws are still on trial, but, as far as experiments go, they are practically sustained. Thus, the results of the first series of experiments of MM. Jacquinot and Frontard, as given by the readings, when reduced to English weights and measures, are as follows:

Normal load, p_n, in pounds per square foot.	Tangential force causing rupture, q, in pounds per square foot.
692	492
2 980	837
5 665	1 196
7 154	1 450

Here p_n and q, the observed quantities of the experiments, have the meanings previously given.

On plotting the values of p_n as abscissas, and the corresponding values of q as ordinates, as shown in Fig. 2, it is found that the straight line,

$$q = p_n \text{ tan. } 8° 15' + 385,$$

very nearly passes through the plotted points. On comparing with the equation,

$$q = p_n \text{ tan. } \phi + k,$$

it is seen that $\phi = 8° 15'$, and $k = 385$ lb. per sq. ft. (cohesion). Mr. Résal, in Table 1, assumes $\phi = 8°$, and computes the corresponding values of k from the last formula, for the simultaneous values of p_n and q observed. The method just outlined seems to the writer to be more satisfactory in its results. In this first series of experiments, the cakes or pats of earth experimented on were very moist, but the apparatus was in order and the results were considered reliable. Cain.

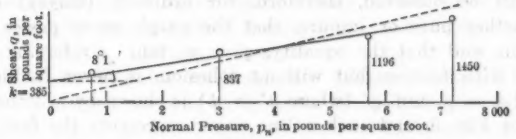

FIG. 2.

In the next series of experiments, the manometers were out of order, and a large correction had to be applied; hence the results are open to doubt, and may not be reliable. The cakes were taken directly from the earthen dam, and they contained "the minimum quantity of water compatible with plasticity". The results are as follows:

Normal load, p_n, in pounds per square foot.	Tangential force causing rupture, q, in pounds per square foot.
3 057	1 036
5 479	1 356
7 740	1 941
9 921	2 288

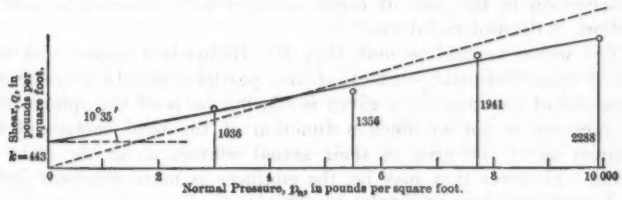

FIG. 3.

The simultaneous values of p_n and q are shown by Fig. 3, and it is found that the straight line that nearly fits the experimental results has the equation,

$$q = p_n \tan. 10° 35' + 443,$$

whence $\phi = 10° 35'$, and $k = 443$ lb. per sq. ft. On plotting to a large scale, the value of k (the intercept of the straight line on the axis of q) and the inclination of the line can be found with all desirable accuracy.

Referring now to Mr. Bell's experiments, of which only a brief summary has been given, it was found by Mr. Bell, in all the experi-

Mr. Cain.

ments on eleven different classes of soils, mainly of clay, that a straight line fitted the plotted results very well in every instance, and, further, that in no case, except for perfectly dry sand, did the straight line pass through the origin; hence the graphs, Figs. 2 and 3, are typical of the results of the experiments thus far performed, and the two laws of Coulomb, with the resulting Equations (1) and (2), seem to be verified.

It will be observed, therefore, for ordinary (clayey) earth or clay, whether pure or impure, that the graph never passes through the origin, and that the equality, $q = p_n \tan. \phi$, referring to earth endowed with friction but without cohesion, is never fulfilled. The graph of $q = p_n \tan. \phi'$ (where $\phi' > \phi$) is shown by a dotted line in Fig. 2, or Fig. 3, and such a line never represents the facts for the materials in question. The attempt to use such a line as a sort of average for the application of the ordinary theory of non-coherent earth would prove futile, because, if x is the abscissa of the intersection of the two lines,

$$q = p_n \tan. \phi' \text{ and } q = p_n \tan. \phi + k,$$

it is seen that when $p_n < x$, the value of q given by the first equation is too small and when $p_n > x$, it is too large. Thus, along a plane of rupture, the resistance to sliding would not be given correctly by the first equation for any value of p_n other than x. From all that precedes, it is evident that the statement of Mr. Green, that, in Fig. 1, "the ratio of Q to P_n is the coefficient of static friction of the material tested" is untenable, and that any attempt to apply such a conception to the case of earth endowed with cohesion as well as friction, is doomed to failure.*

The writer is glad to note that Mr. Richardson agrees with him that a more intimate contact of the particles should increase the coefficient of cohesion for a given earth, but he is of the opinion that the increase is not so much a function of the total surface of the particles as of the area of their actual contact along the plane of sliding. However that may be, the engineer is more especially interested in the experimental values.

At first sight, from examination of Figs. 2 and 3, the assumption does not seem to be realized, but it is possible that the results have not been interpreted aright. In fact, Résal suggests, in connection with the results pertaining to Fig. 3, that possibly, if ϕ was assumed equal to 8° 32′ (tan. $\phi = 0.15$) and the successive values of k are computed from the equation, $k = q - p_n \tan. \phi$, giving 578, 533, 780, 799 lb. per sq. ft., corresponding to the increasing values of p_n pre-

* The theory of coherent earth is complicated, but the writer, in his "Earth Pressure, Retaining Walls and Bins" (recently published by John Wiley and Sons), has been enabled, by aid of Mohr's "Circular diagram of stress" to develop it in the simplest and most practical manner. It is thus available whenever the coefficients, $f = \tan. \phi$ and k for the particular earth, have been ascertained by experiment.

viously given, that the (generally) increasing values of k might represent more nearly its true values. Mr. Cain.

So far as the value of q (the vital thing in earth pressure theory) is concerned, either method leads practically to the same value of this factor; so that the theory of earth pressure, which is based on the constant values of ϕ and k, as found in Fig. 3, is seen to be valid.

The supposed increase of k with the normal pressure received a striking confirmation in experimenting with the earth after it had been energetically rammed for 4 hours, when it was found that the coefficient of cohesion had about doubled.

The engineers likewise subjected the cakes or pats of earth to lateral unit pressures, two and three times as much as the normal unit pressures, the lateral pressures being exerted for an hour, then released and repeated, to consolidate the pat more thoroughly. As a result, the cohesion was found to have increased 60%, if tan. ϕ is assumed to be equal to 0.17 ($\phi = 9° 39'$).

It is a matter of great practical importance to know how to increase the coefficient of cohesion, and these experiments indicate that ramming, with use of water, will effect a material increase. With filling behind a retaining wall, well rammed and thoroughly drained, as in Mr. Lindenthal's design previously noted, the thrust of the earth should be materially decreased, and there is every prospect that the decrease may be permanent.

The writer has read with great interest the "Progress Report of the Special Committee to Codify Present Practice on the Bearing Value of Soils for Foundations",* in which the classification of soils has been done in a scientific manner, and will afford a working basis for the complete investigation of their properties, which it is to be hoped, will be carried forward, with liberal aid from the Society, to a successful conclusion. The "water content" of soils is often very loosely described, and, for definiteness, it is desirable that the tentative classification† of the Special Committee on Soils be adopted, at least temporarily.

The report of the "U. S. Bureau of Standards Sub-Committee", on Earth Experiments and Apparatus,‡ leads one to hope, from the thorough manner in which the preliminary testing of gauges, etc., is being done, that reliable practical results may be forthcoming. The wall friction, possible arching of the material in confined spaces, and even minute movements of the earth particles next the diaphragm, are bugbears to the experimenter; all of which are being investigated carefully by the Sub-Committee.

---

* *Proceedings*, Am. Soc. C. E., for March, 1916, p. 343.
† *Ibid.*, p. 347.
‡ *Ibid.*, p. 353.

Mr. Cain.

In this report, the rotating gauge, Fig. 1 (c),* particularly appealed to the writer, because it seems to offer a very promising method of determining the simultaneous values of f and k for any earth. Thus, let the circle, Fig. 4, of radius r, represent the rotating disk in place, its cup-like top being filled with earth, which, in the rotation, rubs against the earth in the cylinder above it, the surface of sliding being a horizontal plane the area of which is that of the circle $= A$, say. If the earth in the cylinder is subjected to pressure, and this is distributed uniformly and acts normally to the circular top of the rotating disk, with intensity, p_n, the total normal pressure is $p_n A$, and the total frictional resistance to the movement is $p_n Af$. By a well-known theorem, the sum of the moments of all the elementary frictional resistances about the center of the circle is precisely the same as if the total frictional resistance was concentrated at a point distant $\frac{2}{3} r$ from the center. Precisely the same reasoning shows that the sum of the moments of all the resistances due to cohesion is the same as if the total cohesion, $k A$, on the circular area, was concentrated at a point distant $\frac{2}{3} r$ from its center.

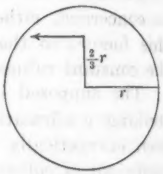

FIG. 4.

Consequently, if M is the torque or moment, due to the external force, about the center of the circle,

$$M = (p_n A f + k A) \frac{2}{3} r;$$

or,

$$q = \frac{M}{\frac{2}{3} r A} = f p_n + k = p_n \tan. \phi + k.$$

Now, this is precisely of the form of Equation (2), so that when various experimental values of q for varying pressures, p_n, have been found, they may be plotted to scale, exactly as in Fig. 2, and probable values of $f = \tan. \phi$ and k may be read off from the resulting graph.

In the foregoing investigation, the thin rim at the top of the revolving disk has been treated as if it was so much earth. If r is regarded as its inner radius, which is that of the upper surface of the earth that revolves, then the right member of the equation before the last, represents the moment of the earth resistance. To this must be added the moment of the friction of the top of the metal rim on the

* *Proceedings*, Am. Soc. C. E., for March, 1916, p. 356.

earth above, $p_n A_1 f r_1$, if A_1 is its area and r_1 is its mean radius; so that the last equation is replaced by, Mr. Cain.

$$q = \frac{M - p_n A_1 f r_1}{\frac{2}{3} r A} = p_n \tan. \phi + k,$$

which is correct for the assumptions made. This apparatus, in operation, causes a lateral pressure to be exerted on the earth corresponding to the normal pressure. It thus corresponds to the actual conditions in a mass of earth subjected to its own weight, or loaded uniformly. To a certain extent, this is true for the apparatus suggested in Fig. 1, but in this there can be no lateral pressure along the edges of the surface of rupture; so that in this respect the former apparatus is superior. It is superior, too, in giving a precise area for the surface of rupture, which cannot be said of Fig. 1, because the earth may spread beyond the confines of the boxes or plaques in which it is placed. However, the results for the plaques are not dependent on a uniform normal pressure, or unvarying coefficients, f and k, along the surface of rupture, because average values for p_n, f, and k are perhaps admissible in Equation (2); but, in the case of the rotary disk, the formula deduced is only compatible with a perfectly uniform distribution of normal pressure and for earth with constant coefficients of friction and cohesion over the whole surface of rupture. Thus, both devices have their drawbacks, and one should be used to check the other.

It is stated that Collin determined the shearing resistance of clay and then afterward, by some independent method, found its coefficient of friction. The writer is unable to see how this latter coefficient can be ascertained with any accuracy by any independent method, and he desires to emphasize the importance of determining the coefficients, f and k, from the same sets of observations as illustrated in the foregoing. In this way, and in this way only (as far as one sees), will the conditions correspond exactly to those in an actual filling behind a wall, or in a mass of earth, or a bank of any character.

In conclusion, it may be added pertinently, that the Society is extremely fortunate in having a highly trained body of scientists, like those connected with the U. S. Bureau of Standards, to undertake this exceedingly difficult subject of pressures in earth. It is needless to say that the writer is much gratified at their quick response to his call for extensive experimenting along the lines indicated in the paper.

The writer has read the discussion by Mr. Goodrich and has also reread the account of Mr. Goodrich's experimenting referred to,* and fully appreciates his efforts to advance our knowledge of the subject of

* *Transactions*, Am. Soc. C. E., Vol. LIII (1904), p. 272.

Mr. Cain.

earth pressure. He believes, however, that a satisfactory theory for ordinary earth must include the influence of cohesion, and that the discordant results found by Mr. Goodrich with different sorts of apparatus may be harmonized when cohesion and all other modifying influences are considered.

Thus, in Fig. 39 of Mr. Goodrich's paper (reproduced herein as Fig. 5), showing one box, with open top and bottom, on top of another with open top and closed bottom, both boxes being filled with earth, on top of which is a weight, it is seen that much of this weight is transferred by friction and cohesion to the sides of this upper box. If no weight is supposed, still, quite a percentage of the weight of earth in the upper box is carried by its sides. In fact, Leygue found,* for a box without a bottom, about 4 in. square in cross-section and 4 in. high, for heights of sand in the box varying from 1.2 to 3.5 in., that from 0.21 to 0.35 of the weight of sand in the box was transferred to the sides of the box. The case is analogous to that of the bin filled with sand, as to which, hundreds of experiments have shown that a part of the weight of the contained material is carried by the sides, and this proportion becomes very large for deep bins filled to the top. In such cases, the weight of earth with its load (if any) causes a lateral thrust which induces the friction on the walls, and this, with the cohesion there (if any), gives the total vertical component of the reaction of the walls. The arching effect of grain in glass bins has been observed by Mr. Ketchum.†

MODEL FOR DETERMINATION OF COEFFICIENT OF INTERNAL FRICTION.

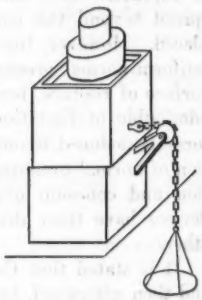

FIG. 5.

Now, recurring to the apparatus, Fig. 5, the weight transferred to the sides of the upper box, does not seem to have been considered by Mr. Goodrich, which invalidates his conclusions, so far as they refer to the experiments performed with this apparatus.

Another source of inaccuracy in any device of this kind (as in the cylinder used by Mr. Bell), where the upper box rests on the lower, is in the friction exerted between the two boxes where they are in contact, when motion is impending from the horizontal force applied. Where an appreciable proportion of the weight of earth and load is carried by the sides of the upper box, this friction may be quite appreciable, and should not be ignored, as is usually done.

* See the writer's paper on "Experiments on Retaining Walls", *Transactions*, Am. Soc. C. E., Vol. LXXII (1911), p. 414.

† Ketchum's "Walls and Bins", p. 323.

Mr. Cain.

The fact that plastic clay acts somewhat like a viscous substance, as stated by Mr. Goodrich, suggests the use of the rotating disk mentioned above to meet the difficulty. There are drawbacks in the case of the plaques, Fig. 1, the rotating disk, or the boxes, Fig. 5, which have been pointed out, and it is to be hoped that some inventor will improve upon all three.

Mr. Goodrich states, with reference to the cigar boxes (respectively 3 and 5 in. deep) filled with sand, that when the boxes "were reversed in position, the angle of tilt at which sliding took place differed". This is evidently because the weight of sand carried by the sides of the top box was different in the two cases, exactly as in the case of the Leygue experiments previously cited.

There can be no objection to the use of the term "internal friction", if it is intended to mean friction, pure and simple, as exerted in the interior of a solid or earth mass. It is used in that sense by Professor Basquin in his notable paper on the "Theory of Internal Friction", and the writer has used it in that sense in his paper on "Experiments on Retaining Walls".* The close agreement found by Professor Basquin in the observed and computed values of the angle of rupture, given in the table quoted, goes far to prove that friction and pure shear (corresponding to cohesion, as previously defined) are exerted at the same time in the materials tested. To that extent, it verifies Coulomb's two laws. In these experiments, the friction is simply proportional to the normal pressure, and the pure shear (or cohesion) varies only with the area of sliding. The total shearing force exerted, sufficient to cause rupture, equals the sum of the two resistances.

Now, unfortunately, Mr. Goodrich does not seem to entertain this view of "internal friction", when earth pressure is in question, but appears to consider it as covering sufficiently both friction and cohesion. Thus he says, where the laws of variation (of cohesion and friction) are practically indentical, "there appears to be no practical reason for not using a single element to include both factors and including both in a common term." Again, he states that the separation "between sliding friction and cohesion is probably unnecessary", and, referring to "internal friction", "that a knowledge with regard to this will make possible a fairly accurate analysis of earth pressures".

The writer feels sure that if Mr. Goodrich will study Figs. 2 and 3 and read the comments thereon, he will change his views. The theories of coherent and non-coherent earth, differ very widely in their results when the cohesion factor is large.† Thus, if the surface of the earth is horizontal, the unit horizontal thrust, q, on a vertical plane in an

* *Transactions*, Am. Soc. C. E., Vol. LXXII (1911).

† The theory of coherent earth is given in full in the writer's recent book on "Earth Pressure, Walls and Bins", from which the formula is quoted, p. 182.

Mr. Cain.

indefinite mass of earth, subjected to no external forces but its own weight, is,

$$q = p\,\frac{1 - \text{sin. } \phi}{1 + \text{sin. } \phi} - 2\,k\,\frac{\text{cos. } \phi}{1 + \text{sin. } \phi}$$

$$= \text{tan.} \left(45° - \frac{\phi}{2}\right) \left[p \text{ tan.} \left(45° - \frac{\phi}{2}\right) - 2\,k\right],$$

where p is the vertical unit pressure acting on a horizontal plane at the depth, x, considered, so that, $p = w\,x$, if w is the weight of the earth per cubic unit. The symbols, k and ϕ, have the meanings previously given. The formula does not apply when q is negative. For this upper portion of the plane, there is no pressure exerted.

This formula does not apply exactly for pressures against a rough vertical retaining wall or the vertical wall of a rough cylinder in which earth is subjected to a vertical unit pressure, p; and neither does the Rankine formula (deduced from it by making $k = 0$) apply exactly; but, suppose earth placed in Mr. Goodrich's cylinder, with the electric buzzer, etc., and that the walls are very, very smooth, so that the friction there is very small and the pressure, p, is applied. Then the foregoing formula would apply approximately; but certainly the Rankine formula does not apply when k is not zero, and any conclusions drawn from it are unwarranted. Thus, the angle of friction cannot be found by using Rankine's formula; the formula for coherent earth alone applies. On substituting several simultaneous experimental values of p and q in this formula, the values of ϕ and k can be obtained from it by trial for the earth experimented on, but the graphical method used by Professor Basquin in the paper previously referred to,* as shown in Fig. 36 of that paper, effects the solution more readily. In this figure, the ordinate at O to the line of slip, AB, measures the cohesion, as defined in this paper. For the bank sand experimented on by Mr. Goodrich, the cohesion thus found is 500 lb. per sq. ft., the angle of friction being $\phi = 32$ degrees. It is seen, from the high value of the coefficient of cohesion, that the Rankine formula is entirely inapplicable.

If the walls of the cylinder are rough, a certain amount of arching of the material is experienced, the pressure transmitted downward is not uniform, and even the formula for coherent earth does not exactly apply.

It may be inferred from the foregoing that the writer is somewhat pessimistic as to the use of gauges in small confined spaces to reach accurate results in estimating earth pressures; still, he hopes that the Special Committee on the Bearing Value of Soils will give the method a fair trial, and will succeed in overcoming the difficulties referred to. If such tests could be supplemented with experiments on retaining

* *Journal*, Western Soc. of Engrs., Vol. XVII, No. 9 (November, 1912), p. 840.

walls, or frames, 6 to 10 ft. high, backed by earth at the limit of stability, the results would be more convincing. Mr. Cain.

Electrical engineers state that there are difficulties in the way of measuring earth pressure by electrical means. If such difficulties could ever be overcome, it would afford an ideal method of finding the lateral pressure at any depth in a mass of earth or against a wall.

The writer trusts that the paper and discussions have shown fully the need for extensive experimentation to determine the coefficients of friction and cohesion in every kind of earth.

His thanks are especially due to the gentlemen who have so kindly engaged in the discussion.

Paper No. 1369

A STUDY OF THE BEHAVIOR OF RAPID SAND FILTERS SUBJECTED TO THE HIGH-VELOCITY METHOD OF WASHING*

By Joseph W. Ellms, M. Am. Soc. C. E., and John S. Gettrust, Esq.

With Discussion by Messrs. George W. Fuller, F. H. Stephenson, E. G. Manahan, George E. Willcomb, H. Malcolm Pirnie, John H. Gregory, F. A. Barbour, George A. Johnson, James W. Armstrong, and Joseph W. Ellms and John S. Gettrust.

Synopsis.

In this paper the writers describe and discuss the development of the high-velocity method of washing rapid sand or mechanical filters, and give a record of a series of experiments obtained in washing a small experimental filter. They also describe the corrosion of a brass wire screen which, in the construction of the filter beds of the Cincinnati, Ohio, Filtration Plant, had been placed between the gravel and sand layers, and for which some other material or some modified form of construction was necessary. Additional observations are given, showing the effect of modifying the depths and sizes of the gravel layers in certain of the Cincinnati filters after removing the brass wire screen.

The paper contains tables compiled from the experimental observations, and there are a number of diagrams and curves illustrating the effect of washing the filter with wash-water at varying rates of

* Presented at the meeting of March 1st, 1916.

flow. The loss of head in the upward flow of the wash-water, produced by the strainers, varying depths and sizes of gravel, and different depths of sand, was given considerable study. The height of flotation of the sand bed during the washing process was carefully measured and recorded, and the effect of a number of factors on the height of flotation of the sand is discussed.

HISTORICAL.

In developing certain features of the design of the rapid sand filters of the Cincinnati Filtration Plant, a series of tests with an experimental filter was made between 1903 and 1905. The results obtained at that time furnished the necessary data on which the design was based. This work was carried out by one of the writers under the direction of George H. Benzenberg, Past-President, Am. Soc. C. E., and an abstract of the data secured may be found in Appendix C of Mr. Benzenberg's report as Chief Engineer of the Commissioners of Water-Works of Cincinnati, Ohio, published in 1909.

One of the principal objects of these early experiments was to determine the effect of various methods of washing the gravel and sand of the filter bed. The methods first investigated were those commonly used at that time. They consisted in forcing wash-water up through the filtering material while stirring the sand bed with mechanically rotated rakes, or by agitating with compressed air blown up through the bed before or at the time the wash-water was being applied. As a result of this preliminary work, another method of agitating the bed was developed. This consisted in forcing the wash-water up through the gravel and sand at such a rate that the sand was floated, thereby agitating and cleansing it in the same operation. This has since become known as the "high-velocity method of washing".

In these early experiments it was soon demonstrated that rotating rakes mixed the gravel and sand layers, and permitted the sand to reach the strainers and clog the openings. It was also found that compressed air blown through the bed had a disturbing influence on the two layers, and caused them to mingle to a greater or less extent. This was due in part to the type of strainers used, to the shallow depth of the gravel, and to its small size. When air and water were used together, the disturbance of the layers was much greater.

The use of wash-water at a rate of from 2.0 to 3.0 cu. ft. per sq. ft. per min. gave only slight evidence in the experimental filter that a mingling of the gravel and sand layers would result from this method of agitation. It was sufficient, however, to make it advisable to adopt precautionary measures in the design, and, with this in view, a method of forcibly holding the gravel in place by a wire-cloth screen was tried. The screen was placed between the gravel and sand layers, and was fastened rigidly. The experimental results obtained with this form of construction were so satisfactory that it was decided to place a similar screen in the large filters of the Cincinnati plant, the construction of which, at that time, was about to be commenced.

The large filter tanks of the plant were constructed with bottoms consisting of parallel hopper-shaped troughs running lengthwise of the tank, and formed by wedge-shaped concrete blocks cast in place. Spaces, 2¼ in. wide, left between the bases of adjoining rows of the parallel ridge blocks, formed the filtered water channels. These channels were covered at the top with perforated brass strainer plates. The tops of the ridges were 12 in. apart on centers, and the space from the strainer plates to these tops was filled with a graded layer of fine gravel. A brass wire-cloth with 100 meshes per sq. in. was bolted to the tops of the ridges, and rested between them on the gravel. The sand layer, having a depth of 30 in., was placed directly on the screen, as shown by Fig. 1.

The high-velocity method of washing, which had been developed experimentally, has been used with marked success during the seven years the Cincinnati Filter Plant has been in operation, and it was not until about two years after the plant was started that anything defective in the construction of the screen system was noted. It was first observed that the screen had pulled away from the bolts where it was attached to the ridges, and also at the ends of the tanks where there was lack of support for the wire-cloth and insufficient means for fastening it. Although the method of fastening the cloth was evidently mechanically defective, and although repairs were promptly made, the breaks became more frequent. It was apparent that some other factor than an inadequate method of fastening must be found to account for the constant breaking of the screen.

A careful examination of the screen showed that the brass wire was corroding, and that the short cross-wires of the cloth were broken more

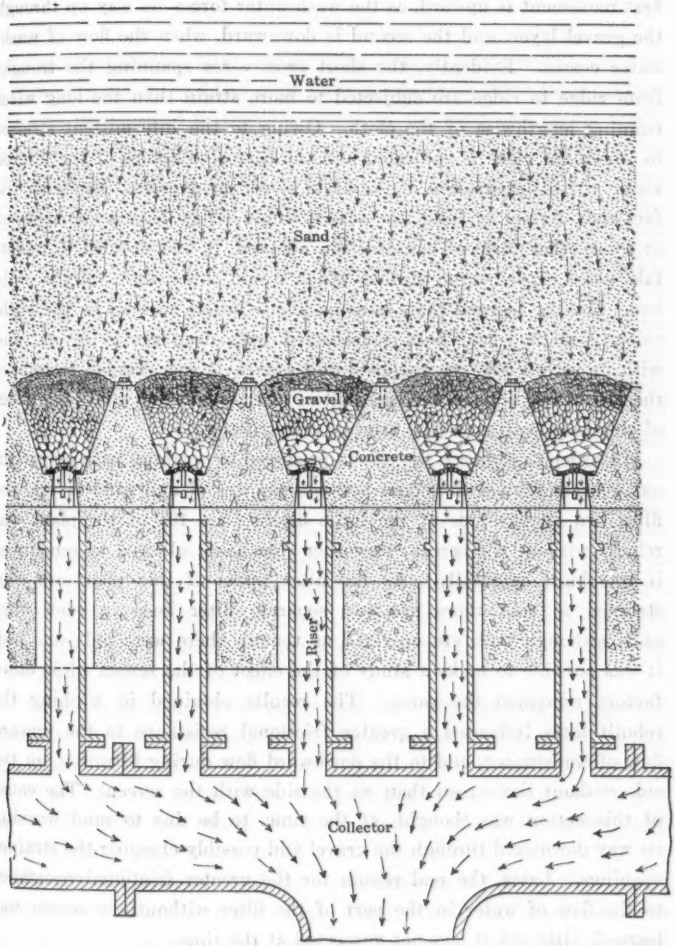

FIG. 1.

frequently than those running lengthwise. A slight movement of the screen, at the beginning and close of a wash, probably occurs. The first movement is upward, as the wash-water forces its way up through the gravel layer, and the second is downward, when the flow of wash-water ceases. Evidently, the short cross-wires spanning the troughs from ridge to ridge are subjected to more strain than the long wires running lengthwise of the cloth. Owing to the intermittent stresses to which the cloth is subjected and the corrosive action of the filtered water, the disintegration of the brass slowly progresses. Realizing the fact that, sooner or later, the screen would either have to be renewed or some other form of construction adopted, it was decided to undertake some experimental studies which would throw light on the problem. Having learned that, in some plants, filters washed by the high-velocity method had been constructed with deep gravel layers, and with no screen between the sand and gravel, it was decided to remove the screen from one of the large filters of the plant and study the effect of this modification of the original construction.

In order to compare the effects produced by washing with and without a brass wire-cloth screen between the gravel and sand layers, the filter bed on one side of the large filters (No. 19) of the plant was rebuilt without the screen, the other side being allowed to remain as it was built originally. As the filter tanks of this plant are constructed so that there are two separate filter beds in each filter unit, although both are operated as though there were only one bed, it was possible to make a study of the effect of the screen while other factors remained the same. The results obtained in washing the rebuilt filter indicated a greater frictional resistance to the upward flow of wash-water, and to the downward flow during filtration, on the side without the screen than on the side with the screen. The cause of this action was thought, at the time, to be due to sand working its way downward through the gravel and possibly clogging the strainer openings. Later, the real reason for the greater frictional resistance to the flow of water in the part of the filter without the screen was learned, although it was not suspected at the time.

On account of the difficulties encountered in working experimentally with these large filter units, in which large quantities of gravel and sand had to be handled and a great deal of time was required to make

the desired changes, it was decided to construct a small experimental filter, similar to the one experimented with in 1903.

The Experimental Filter.

The experimental filter was built of 2-in. cypress lumber. It was 3 ft. square inside, and had plate-glass windows on three sides. These windows were placed so that the action of the sand and gravel would be visible. The filter was constructed so as to be an exact vertical section of the hopper-shaped troughs and strainer-plate system used in the large 4 000 000-gal. units of the Cincinnati Filtration Plant. Holes were bored at convenient points on one side of the tank, and glass gauge tubes were attached to fittings screwed into these holes. The height to which the water rose in these tubes was the measure of the pressure, in feet of water, at the point where the gauge was attached. Fig. 2 is a section through the filter showing the principal dimensions and also the location of the various gauges. The hopper-shaped troughs which hold the gravel were of the same shape and size as those in the large filters. The strainer plates used were also the same as those in the large filters. These plates were of brass, and had four rows of $\frac{3}{32}$-in. holes punched in them, each hole being $\frac{3}{4}$ in. from adjacent holes. The combined area of the openings in the strainer plates was 0.3% of the sand area of the filter. There were two gutters for draining off the wash-water, their sides being at an angle of 45° to the side of the filter tank. These gutters in the experimental filter differed from the deep gutters with straight sides which are used in the large filter units of the plant.

All the experiments were made with the water entering and leaving the filter in a reverse direction to that followed by the water during the process of filtration, that is, all experiments were made by washing the filter. As this process lifts the sand and causes it to move up and down, it is the one which is most likely to cause the gravel and sand to mix.

In measuring the flow of the wash-water to the filter, the writers used a 3-in. Worthington turbine meter which was purchased and calibrated expressly for this purpose. The wash-water was delivered under the strainer plates at four points at the bottom of the filter. The head, in feet of water at various points in the filter during the process of washing, was measured by the eight gauge glasses pre-

viously described. Back of these gauge glasses there were scales painted white, and marked off in feet and tenths, and these were set so that the zero point of each was at the same elevation. This datum line was taken arbitrarily at the inside bottom of the filter tank, all

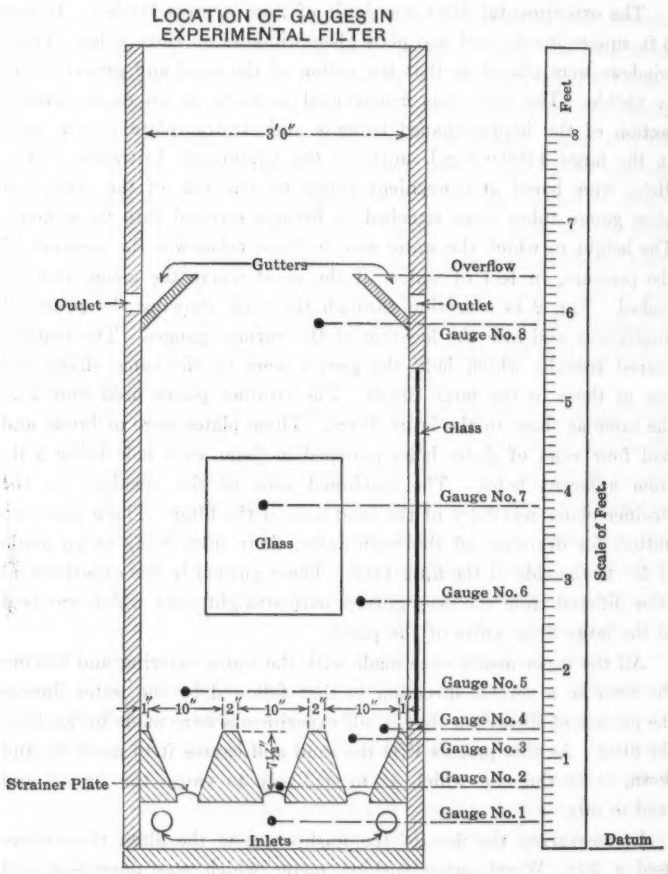

FIG. 2.

readings of the various gauges being in feet above this point. Gauge No. 1 was set under the strainer plates, at Elevation 0.3, and was approximately 0.3 ft. below them. This gauge gave a measure of the total head required to force the wash-water through the filter. Gauge

No. 2 was set immediately above the middle strainer plate, at Elevation 0.68. For a given quantity of wash-water passing through the filter, the difference in the readings between Gauges Nos. 1 and 2 gave the loss of head through the strainer plates. Gauge No. 3 was set at Elevation 1.23, so as to be just below the brass wire screen used to separate the 7½ in. of gravel from the sand. Gauge No. 4 was set at Elevation 1.32, so as to be just above the screen. Gauge No. 5 was set at Elevation 1.75, and was at the dividing line between the sand and gravel when 14 in. of gravel were used. Gauges Nos. 6, 7, and 8 were set, respectively, at Elevations 2.75, 3.82, and 5.84. Gauge No. 8 was placed so as to be above the floating sand and thus give a true measure of the elevation of the top of the water in the filter. The top of the gutters was at Elevation 6.38.

In making the tests, ordinary washed river sand was used, the mechanical analysis being given by Fig. 3. The sand had an effective size of 0.41 mm. and a uniformity coefficient of 1.41.

Conditions Under Which the Various Tests Were Conducted.

The writers state the results of seventeen tests with the experimental filter, and in Table 1 give the conditions under which these various tests were conducted.

TABLE 1.—Conditions Under Which Tests were Conducted.

Test No.	Depth of gravel, in inches.	Depth of sand, in inches.	Remarks.
1	None.	None.	Strainer plates only in place.
2	7½	None.	Strainer plates and gravel in place.
3	7½	None.	Brass wire screen placed over gravel.
4	7½	20	Brass wire screen between sand and gravel.
5	7½	25	Brass wire screen between sand and gravel.
6	7½	30	Brass wire screen between sand and gravel.
7	7½	20	No screen between sand and gravel.
8	7½	25	No screen between sand and gravel.
9	7½	30	No screen between sand and gravel.
10	14	None.	No screen.
11	14	20	No screen between sand and gravel.
12	14	25	No screen between sand and gravel.
13	14	30	No screen between sand and gravel.
14	18	None.	No screen.
15	18	20	No screen between sand and gravel.
16	18	25	No screen between sand and gravel.
17	18	30	No screen between sand and gravel.

Note.—For each of these tests, a tabulation of the data may be found on the "test sheet" having the same number as that of the test; and plotted curves of the data will be found on the "curve sheets" having numbers corresponding to those of the tests. The details of Tests Nos. 5, 8, 12, and 16, however, are omitted in the paper, as they show the conditions in washing with a depth of 25 in. of sand. The conditions of washing for 20 and 30 in. are shown in the other tests, and there are no marked characteristics for the 25-in. depth which are not indicated by the tests for the 20 and 30-in. depths.

When a depth of 7½ in. of gravel was used, it was graded and placed as follows:

First layer: 1-in. layer (hand-placed) that passed a 1-in. mesh sieve and was held on a ½-in. mesh sieve;

Second layer: 6 in. of gravel that passed through a ½-in. mesh sieve and was held on a sieve with 10 meshes per lin. in.;

Third layer: ½-in. layer of gravel that passed a 10-mesh sieve and was held on a sieve with 12 meshes per lin. in.

This arrangement of the gravel was the same as in the original construction of the 4 000 000-gal. filter units.

When a depth of 14 in. of gravel was used, it was graded and placed as follows:

First layer: 2 in. of gravel (hand-placed) that was held on a 1-in. mesh screen but would pass through a 2-in. mesh screen;

Second layer: 2 in. of gravel that passed a 1-in. mesh screen and was held on a ¾-in. mesh screen;

Third layer: 3 in. of gravel that passed a ¾-in. mesh screen and was held on a ½-in. mesh screen;

Fourth layer: 3 in. of gravel that passed a ½-in. mesh screen and was held on a ¼-in. mesh screen;

Fifth layer: 4 in. of gravel that passed a ¼-in. mesh screen.

When a depth of 18 in. of gravel was used, it was graded and placed as follows:

First layer: 2 in. of gravel that was held on a 1-in. mesh screen but would pass through a 2-in. mesh screen;

Second layer: 3 in. of gravel that passed a 1-in. mesh screen and was held on a ¾-in. mesh screen;

Third layer: 3 in. of gravel that passed a ¾-in. mesh screen and was held on a ½-in. mesh screen;

Fourth layer: 4 in. of gravel that passed a ½-in. mesh screen and was held on a ¼-in. mesh screen;

Fifth layer: 6 in. of gravel that passed a ¼-in. mesh screen.

Method of Making Observations.

In making the tests, a 2-in. gate-valve, which admitted the wash-water under the strainer plates, was gradually opened enough to give sufficient upward velocity to the wash-water to cause flotation of all

the sand in the filter. Readings of the eight gauges were then recorded as shown by the height of the water in them, and readings of the water meter were taken at the start and finish of the observations made with a certain rate of flow of the wash-water. The time interval between the readings of the meter was taken with a stop-watch. The height to which the sand floated during the washing process, above that which it occupied when the filter was idle, was measured by observations through the plate-glass windows. Measurements were also made by using small metal cups, open at the top and arranged on a steel plate so that the top of the lowest cup was 2 in. from the bottom of the plate, the top of each cup being 2 in. above the top of the next lower one. The arrangement of this apparatus is shown by Fig. 4.

When starting a test, the bottom edge of the sand catcher was placed level with the surface of the sand as it lay in its normal position after being washed and hydraulically graded. The height to which the sand floated could be determined within less than 2 in. by withdrawing the cups from the filter at the close of the test and noting the height, in inches, from the bottom edge of the plate to the top of the highest cup which was filled with sand. During most of the tests, the water was clear enough to read the height of the sand without withdrawing the cups, and it was possible to interpolate readings of the height between adjacent cups.

In conducting a test, the upward velocity of the wash-water was increased step by step, readings being taken as previously stated, and was finally increased to about 2.1 ft. per min., the latter rate being as great as it was possible to obtain. The supply of wash-water was obtained from the same source as that which furnishes the wash-water for the 4 000 000-gal. units of the filter plant. These large filter units are washed with an upward velocity of the wash-water of 2 ft. per min. This rate is calculated from the area of the filter unit and the quantity of water used per minute in washing. No allowance is made for the space taken by the sand particles or by the wash-water troughs.

The wash-water used was filtered water which had been raised by centrifugal pumps to an elevated reservoir. This reservoir has an overflow, thus making it possible to operate one of the centrifugal pumps continuously and thereby maintain a constant head in the wash-water tank while making tests with the experimental filter. The

water from the overflow of the wash-water reservoir passes back through a pipe line to the suction well of the pumps. The washing of the large filter units was suspended while a test was being made with the

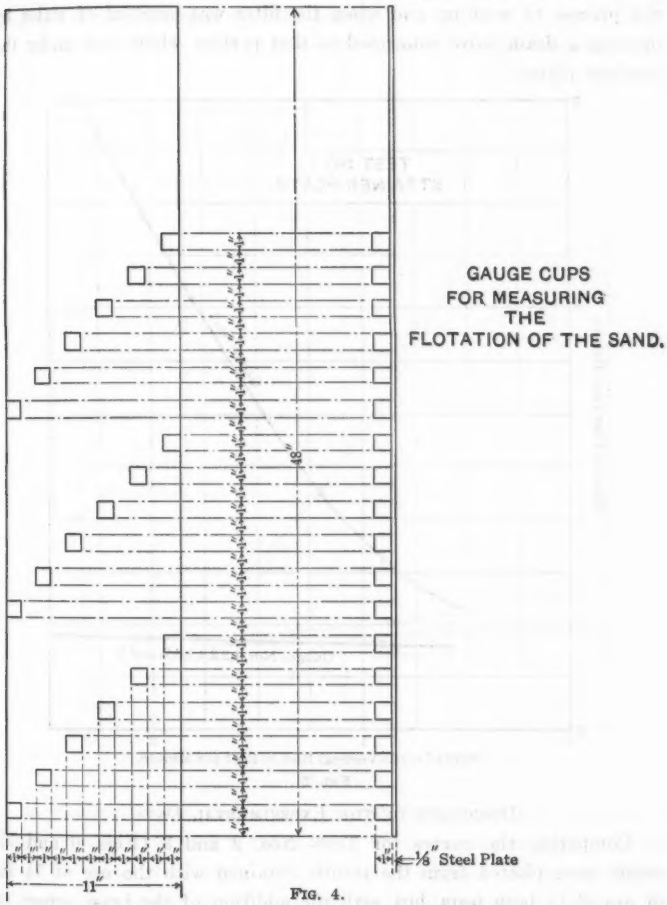

FIG. 4.

experimental filter, so that there would be no variations in the upward velocities of the wash-water in the latter on account of changes in the acting head, except those purposely made by the person conducting the test.

During all the tests the effect on the sand and gravel was observed carefully through the plate-glass windows. The behavior of the sand and gravel at the plane dividing them was noted, particularly during the process of washing and when the filter was emptied of water by opening a drain valve connected to that portion which was under the strainer plates.

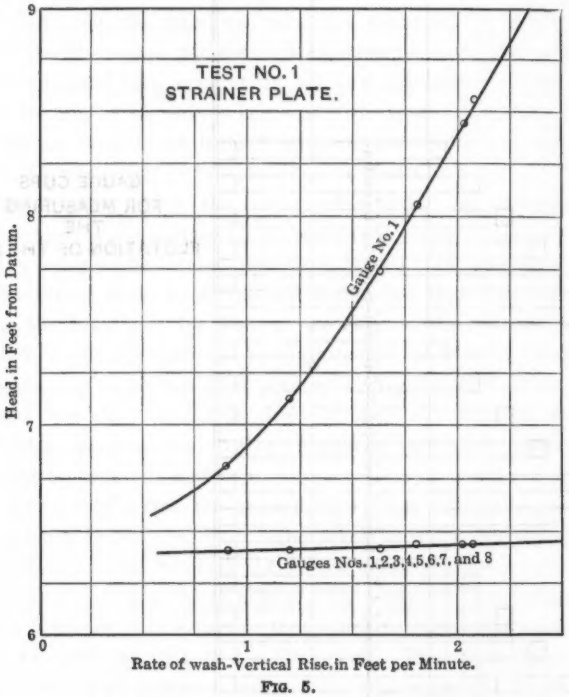

FIG. 5.

DISCUSSION OF THE EXPERIMENTAL DATA.

Comparing the curves for Tests Nos. 2 and 3 (Figs. 6 and 7), which were plotted from the results obtained with the use of 7½ in. of gravel in both tests, but with the addition of the brass screen in Test No. 3 and without it in Test No. 2, it is evident that the introduction of the screen added very little to the head necessary to force the water through the filter. The head, as recorded by Gauge No. 3, which was directly below the screen, was identical for the two tests.

Gauges Nos. 1 and 2 showed a head approximately 0.02 ft. higher in Test No. 3 made with the screen, than in Test No. 2 made without the screen. The screen used was new, and the openings between the wires had not become plugged up with gravel.

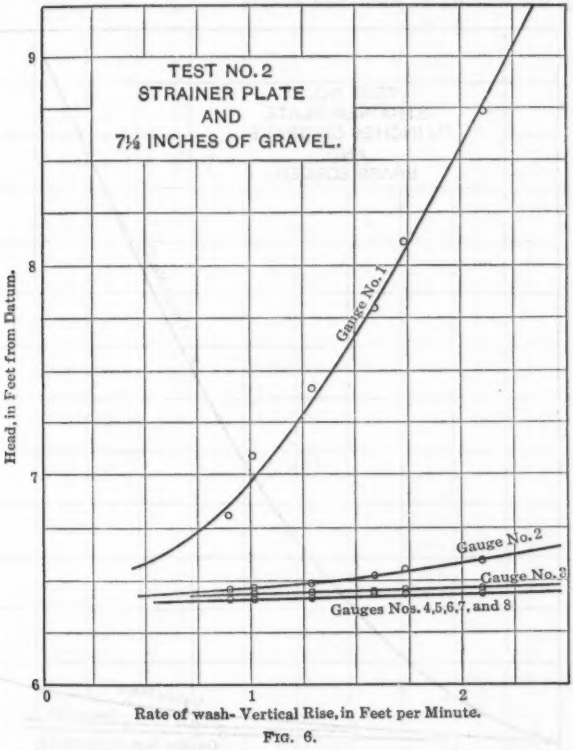

FIG. 6.

A comparison of the curves plotted from the data obtained in Tests Nos. 4, 6, 7, and 9 (Figs. 9 to 11, inclusive) in which 20 and 30 in. of sand were used, both with and without the screen, shows that, for the same depth of sand, the total head necessary to force the wash-water through the filter, at equal upward velocities, was practically the same with or without the screen. Gauges Nos. 2 and 3 showed a slightly increased loss of head in the three tests without the screen over those with the screen. The tests with the screen were con-

ducted previously to those without the screen. It is probable that, in walking over the gravel when the screen was removed, the gravel around the gauge outlets was disturbed and became lodged in such a position as to cause the upward velocity of the wash-water to increase slightly the reading of these two gauges.

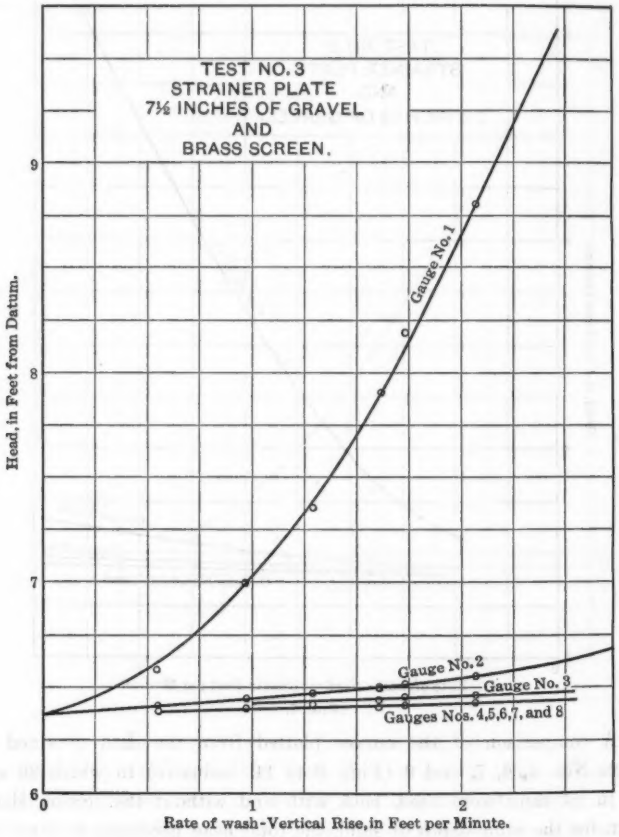

FIG. 7.

In Test No. 5 (the curves for which are not reproduced herein), with an upward velocity of the wash-water of 1.6 ft. per min., the pressure on Gauge No. 7 began to increase rapidly. At this point the

per min., so that the rising wash-water would be mixed with the air trapped under the strainer system and in the gravel and sand of the filter bed. These conditions are the most severe to which filter sand and gravel can be subjected in practice, as the escape of the air and water together lifts the sand bed bodily at first, followed almost immediately by explosive discharges of air and water at points of least resistance on the surface of the sand. When the filter was drained, by allowing the water to pass downward through the sand and gravel and flow out through the 4-in. discharge pipe under the strainer system, observations through the glass windows showed that the sand was not carried downward into the gravel. It is obvious that, if the mixing of the sand and gravel is to be prevented, the latter must be graded properly from the bottom layer to the sand line.

In order to compare the losses of head through the various portions of the filter under different conditions, Table 2 has been arranged with data taken from the curve sheets. This table was compiled from all the tests in which sand was used in the filter, and the data are tabulated for upward velocities of the wash-water of 1.0, 1.5, and 2.0 ft. per min. The column, "Loss of Head Through Filter", was obtained by taking the difference between the height of the water flowing over the gutters and the reading of Gauge No. 1. The column, "Loss of Head Through Strainer Plates", was obtained by taking the difference between Gauges Nos. 1 and 2 in the various experiments when the sand and gravel were in place. These figures for the loss of head through the strainer plates differ from those obtained when there was no gravel over the strainers. The gravel closes some of the openings in the strainer plates, and thereby causes an increase in the loss of head through them for the same upward velocity of the wash-water.

The loss of head through the gravel was obtained from the difference in readings between Gauge No. 2 and some gauge above the gravel layer. These readings for the loss of head through the gravel were taken from the tests made before the sand was placed over the gravel. The column, "Loss of Head Through Sand", was obtained by taking the difference between the "Loss of Head Through Filter" and the sum of the losses of head through the strainer plates and gravel. These results have been plotted in the form of curves on Fig. 18.

* Brass wire screen in place

† Fine sand passed over wash-water troughs.

The curves for the loss of head through the strainer plates, through the gravel, and through 20, 25, and 30 in. of sand for the same depth of material, are the averages for the losses recorded in Table 2. The curves for the loss of head through the entire filter are not averages, but represent the curves for the individual tests. The curves for the loss of head through the entire filter, when using 7½ in. of gravel, and 25 and 30 in. of sand, were omitted on this curve sheet, as they crossed other curves and confused the lines.

It is seen from these curves that the loss of head through the gravel was a very small part of the total loss of head through the

filter. With an upward velocity of the wash-water of 2 ft. per min., the loss of head through the strainer plate was 2 ft.; through the 30 in. of sand, the loss of head was 2.2 ft., when washing at a rate of 2.0 ft. per min. From a study of these curves, it is interesting to note the effect on the loss of head through the sand of changes in the upward velocity of the wash-water. The loss of head through the sand increased very slowly as the upward velocity of the wash-water increased. The wash-water pushed the sand grains farther apart as the velocity increased, and more water flowed through the sand bed, but with very little increase in the loss of head through the sand.

Fig. 19 has four curves, three of which are from experiments in which the sand had an effective size of 0.41 mm. The other curve is taken from another set of experiments in which was used a 30-in. depth of sand which had an effective size of 0.31 mm. (Fig. 20 shows the mechanical analysis of this sand.) These curves represent the average of the distances obtained in the various tests between the top of the floating sand during the process of washing and the normal level of the sand when compacted during the process of draining. They also show that the height of flotation of sand having the same effective size, and subjected to the same upward velocity of the wash-water, was proportional to the depth of the sand. An analysis of the coarser sand used in these experiments is shown by Fig. 3.

When using the finer grade of sand in the filter, the height to which the sand floated was greater than that obtained with the coarser sand. This is shown by the curve for the rise of the sand with an effective size of 0.31 mm. With an upward velocity of the wash-water of 2 ft. per min., this difference amounted to 4½ in. On a number of tests with the large 4 000 000-gal. filter units at the Cincinnati Filtration Plant, a rise of 20 in. of the sand was obtained with an upward velocity of the wash-water of 2 ft. per min. The sand in these filters has an effective size of 0.39 mm., and a uniformity coefficient of 1.35. The measurement of the rise of the sand in the large filter units was made during the regular process of washing, after the filter had been removed from service on account of the accumulation of sediment in the sand bed. In this case the sand was dirty, whereas, in the set of experiments with the experimental filter, the sand was clean, due to the fact that it was continuously subjected to the washing process with filtered water, and was not used to filter water containing sediment.

OBSERVATIONS ON THE ORIGINAL AND ON TWO RECONSTRUCTED FILTER UNITS OF THE CINCINNATI FILTER PLANT.

The large filter units are 50 ft. long, and each half of the unit is 14 ft. wide. The wash-water gutters (Fig. 6) are 14 ft. long and 18 in. wide, and run the width of the filter. There are six of these gutters in each half of the filter unit, and the area covered by them is 18% of the sand area of the filter. The upward velocity of the wash-water is computed from the volume of water used per minute and the sand area (1 400 sq. ft.) of the filter. During the washing process, when the sand rises between the parallel sides of the gutters it reaches a body of water which is moving upward with a greater velocity than that below the gutters, on account of the decreased sectional area. Taking this fact into consideration, and correcting for the change in the upward velocity of the wash-water between the gutters, the measurements made on the large filter units for the rise of sand agree more nearly with the results obtained in the experimental filter.

The large filter unit (No. 19), from which the screen had been removed on one side and with which experiments had been attempted, was examined carefully in order to find what caused the side without the screen to wash so poorly and the water to drain out so slowly. The trouble was found in the strainer plates. In replacing these plates, workmen had used a cloth in some places to wipe off the cement from the top of the plates. This had forced some of the wet cement into the small openings of the strainer plates, where it had hardened and thus plugged them up. After cleaning out the holes in the plates, both sides of this filter were rebuilt without using the brass screen, 14 in. of gravel being used and placed as recorded in Test No. 10.

The original sand was placed on top of the gravel, which gave a depth of 30 in. to the sand layer. When the filter was washed with water having an upward velocity of 2 ft. per min., the sand flowed over the edges of the gutters. In order to prevent the loss of sand. the maximum upward velocity of the wash-water was reduced to 1.5 ft. per min., when estimated on the basis of the sand area. Fig. 6 shows the heights to which the main body of the sand floated in the 4 000 000-gal. filter units with upward velocities of the wash-water of 1.5 and 2 ft. per min.

Loss of sand over the edges of the gutters took place in the large filter units when the main body of the sand floated farther below the

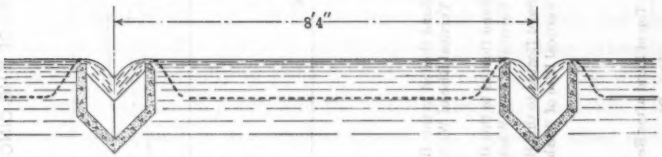
FIG. 21.

gutter edges than it did in the experimental filter. The reason for this is discussed in a subsequent paragraph.

The distance between the edges of the two gutters in the experimental filter was only 2 ft., but, in the large filter units of the plant, this distance is 6 ft. 10 in. The velocity of the water in the latter case is greater in the vicinity of the gutters than when the latter are closer together. The effect of the increased velocity of the wash-water in the vicinity of the gutters is to carry the sand over with the water. The difference in velocity is shown clearly during the process of washing a filter. The muddy water rising from the sand during the first part of the wash, and which is nearest to the gutters, commences to pass over into them when the upper surface of the main body of the rising sediment has still 8 or 10 in. to travel before reaching the surface of the water. Fig. 22 represents the effect of the increased velocity of the water in the vicinity of the gutters.

RISE OF SEDIMENT DURING PROCESS OF WASHING.



The dotted line represents the surface of the muddy water rising from the sand during the first part of the wash. The muddy water nearest the gutters is just passing over, and the greater part of the rising sediment between the two gutters has from 8 to 10 in. more to rise before reaching the surface.

FIG. 22

Another factor, which has an influence on the sand being carried over into the gutters in the large filters when it reaches a certain height, is the shape of the sides of the gutters. From Figs. 6 and 7 it will be seen that the gutters used in the large filter units are pointed at the bottom, and that they have perpendicular sides, whereas the sides of the gutters in the experimental filter sloped at an angle of 45 degrees. During Test No. 17 with the experimental filter, some of the sand passed over the gutters and the main body of the sand remained about 0.5 ft. below their tops. It could be seen that the sand which floated into the gutters came from the main body of the sand immediately below their outer edges, and through the zone of highest velocity of the wash-water. The material which escaped was only the finest sand particles, or silt.

Filter No. 5 was rebuilt, using 7½ in. of gravel and 30 in. of sand, but without the brass wire screen. The 7½ in. of gravel were placed as recorded in Test No. 2. Both filters—Nos. 5 and 19—have been in service for more than a year. From time to time, holes have been dug at various places in both these filters, and they have been examined carefully to see whether the sand was working its way down into the gravel. Thus far, they have been found to be in perfect condition, and their behavior in operation has been entirely satisfactory.

Conclusions Reached Relative to Reconstruction of All Filter Beds in Cincinnati Filter Plant.

The gravel in a rapid sand filter has three functions: It supports the sand layer; acts as a distributor of the rising wash-water, thereby making the upward pressure more uniform under the sand layer; and prevents the sand from passing downward to the strainer plates and clogging their openings. If these are the conditions which must be met, the practical questions to be decided relate to the total depth and the proper sizes of the stones forming the gravel layer.

The data collected during these experiments appeared to the writers to be sufficient to answer these questions, and, in consequence, the reconstruction of all the filter beds has been undertaken.

The 7½ in. of gravel used in the tests and in Filter No. 5 had proved successful, as also had the 14 in. of gravel used in Filter No. 19. Gravel, as it is pumped and screened on barges in the Ohio River near Cincinnati, contains all the material that will pass through a 2-in. hole.

Starting with gravel having an approximate diameter of 2 in., it would be possible to build an effective gravel bed with a depth of only 5 in. In the large filter units, it is necessary for the men who are placing the gravel to walk on it while they spread it out with rakes. It was decided, therefore, to build the gravel bed so deep that there would be no trouble due to the mixing of the different layers of gravel by the men walking on it, and the 14 in. of gravel used in Test No. 10 was decided on as giving a sufficient factor of safety in this respect.

In any gravel layer, acting as a support for the sand of a filter, there must be, of course, a rather uniform gradation from the coarsest to the finest particles, in order that the penetration of the smaller stones of the layer of gravel above into the voids at and near the surface of the layer below shall not be too great. This fact was taken into consideration in selecting the screens used for separating the

various sizes of gravel desired. Consideration was also given to the various sizes of gravel which could be obtained by screening washed Ohio River gravel as it was commonly sold, so that as little waste of material as possible should result.

The sand layer placed on the 4-in. gravel layer which had passed a ¼-in. mesh screen is washed in the filter in the usual way. This produces a gradation of its particles which merges them into the gravel layer beneath and thus forms a uniformly graded whole, commencing at the strainer plate with the 2-in. stones and ending with the finest sand at the surface of the bed.

The estimated cost of renewing the brass wire screen and of placing the filters of the Cincinnati Filter Plant in the same condition as that in which they were originally was more than $15 000. To have improved on the imperfect method of fastening the screen would have probably cost from $5 000 to $10 000 additional, or a total of from $20 000 to $25 000, depending on the improved method adopted.

From carefully kept cost records of the various operations required in rebuilding the filter beds, and including the cost of extra gravel, which is obtained for $1.39 per ton, the average cost for reconstructing each filter bed is $280. This makes the total cost of rebuilding the beds $7 854, to which should be added $650 for half the time of a foreman in supervising the work. The total cost, therefore, will be approximately $8 500, as compared with $20 000 or $25 000 for a renewal of the brass wire screen and improved methods of fastening it. As corrosion of the screen was inevitable, and as, by the substitution of a deeper gravel bed for the screen, the elimination of the latter was found to be possible, it seems that the problem has been satisfactorily solved.

Conclusions.

The conclusions reached as a result of the experimental work and of the writers' observations of the large filters of the Cincinnati plant may be briefly summarized as follows:

1.—In washing a rapid sand or mechanical filter, at rates of from 1.0 to 2.0 ft. vertical rise of the wash-water per minute, the greatest losses of head occur in the strainer system and in the sand.

2.—The loss of head through the strainer system used (which had openings equal to 0.3% of the sand area of the filter) was never greater than 2.22 ft., even with a velocity of the wash-water of 2.0 ft. per min.

With other forms of strainer systems and with different areas of openings the losses of head would differ, of course, from those found, even with the same velocities of wash-water.

3.—The loss of head in the gravel layer was found to be less than ½ ft. even with a velocity of the wash-water of 2.0 ft. per min. and with a gravel layer 18 in. deep.

4.—The loss of head through the sand did not exceed 2.37 ft. with a depth of 30 in. of sand and with a rate of flow of the wash-water of 2.0 ft. vertical rise per minute.

5.—The height of flotation of the sand during the washing process is affected by the depth of the sand, by its fineness, and by the velocity and uniformity of distribution of the wash-water. It is proportional apparently to the depth of the sand bed, other conditions being equal. Loss of sand over the edges of the waste troughs, during the washing process in the Cincinnati filters, was found to be influenced by the increased velocity of the wash-water, produced by the submergence of the gutters in the rising wash-water and by the distance of the floating sand from the bottom and sides of the gutters. Submergence of the gutters in the floating sand is undesirable.

6.—It was found that a properly graded layer of gravel would act as a distributor of the rising wash-water; and that layers as deep as 18 in. produced very low losses of head. Gravel layers 14 in. deep, and graded carefully in size from stones 2 in. in diameter at the bottom to particles that had passed through a ¼-in. mesh sieve at the top, were adopted as affording a sufficient margin of safety against improper grading in placing, or disturbance by wash-water moving at high velocity through the gravel.

7.—It was found possible, by introducing the deeper gravel layers in the Cincinnati filters, to do away with the brass wire screen originally placed between the gravel and sand, and which, although it provided at first a positive method of preventing the gravel and sand layers from becoming mixed, developed in the course of two or three years a mechanical weakness, due to imperfect methods of fastening and to disintegration of the brass itself by corrosion, thereby making it useless.

8.—The cost of renewal and of improving the method of fastening the brass wire screen in the Cincinnati filters was estimated to be nearly two and one-half to three times the cost of rebuilding the filters with deeper gravel beds, and the latter method, therefore, was adopted.

DISCUSSION

Mr. Fuller.

GEORGE W. FULLER,* M. AM. SOC. C. E. (by letter).—The authors of this paper have presented interesting and instructive data relative to important aspects of cleaning mechanical filters, especially with the aid of construction details, adopted not only at the Cincinnati plant, but also for those at New Orleans, Louisville, Minneapolis, Grand Rapids, and Evanston.

One of the difficulties which the screen at the top of the gravel in the original design was supposed to correct was doubtless caused by the jet action of the entering wash-water. In consequence of this action, the upper layers of the smaller gravel were seriously disturbed when the total thickness of the layer of gravel was no greater than in the original construction at Cincinnati. The effect of the deeper gravel layers, as interpreted by the writer, is essentially to prevent jet action and thus effect a substantial elimination of the disturbance more or less irregularly of the finer upper gravel layers.

In the earlier designs at Cincinnati, New Orleans, and Louisville, very little trouble with this type of strainer system design seems to have been caused by the quality of the metal, which was what might be briefly designated as "common brass". In the later designs, particularly at Minneapolis and Grand Rapids, effort was made in the direction of improvement, and bronze, instead of brass, was specified for the perforated plates at the bottom of the gravel and the bolts for holding these plates in place. Under the same specifications, practically speaking, serious trouble from breakage of plates and bolts resulted at Minneapolis; but at Grand Rapids there was practically no trouble, as was the case at Cincinnati, New Orleans, and Louisville. At Evanston, difficulties arose, not with the plates, but with the bronze bolts, and Monel metal was finally substituted for these.

In more recent designs it has been the writer's custom to use, not this type of strainer system, but perforated pipe in which the holes are staggered on the lower quadrant. This allows the wash-water to enter the filter in a downward direction about 45° from the horizontal, with the result that the entering stream strikes the filter floor and is deflected upward as a broken stream substantially free from jet action. This type of strainer system was probably first used by James H. Fuertes, M. Am. Soc. C. E., at Harrisburg, Pa., in 1905. The writer used this perforated pipe strainer system with success in a plant built in Burlington, Vt., in 1907, and in another plant, built at about that time, for the Botany Worsted Mills, Passaic, N. J. So far as known, no trouble has been experienced in any of these plants, but it is probably wise to provide somewhat deeper gravel layers than was

* New York City.

the custom in 1905 when the original design for the Cincinnati filters was made. Mr. Fuller.

It is worthy of note that, in the Ira H. Jewell *vs.* Minneapolis filter patent suit, the United States District Court at Minneapolis, in August, 1915, decided that the brass wire screen, such as used in the Cincinnati filters, infringes Claim No. 14 of Letters Patent No. 649 411 which is adjudged valid.

F. H. STEPHENSON,* M. AM. SOC. C. E. (by letter).—It was the writer's privilege to be closely connected with the construction of the Cincinnati Filter Plant, both before and after the filters were put into service. While the wire screens were being placed, certain predictions were made relative to their life, which, according to the prophets, ranged from 3 months to 5 years. Some difficulties were encountered in trying to fasten the screens securely to the ridges and, at the same time, keep the screens stretched tightly over the gravel. It took 40 man-hours to place the screens in one filter unit. Mr. Stephenson.

The writer has been converted to the idea of not being too insistent about keeping down the uniformity coefficient of the sand, and thinks the authors have shown that the larger particles settle out at the first wash and mingle with particles of similar size in the gravel layer. Some of the analyses made when the sand was being placed in the filters show an effective size of 0.33 mm. and a uniformity coefficient of 1.60. The writer recalls that the filters were washed and the top ½ in. of sand scraped off and wasted. That the sand in the filters now has an effective size of 0.39 mm. would indicate that some of the finer particles had been carried off during the many washings, even though the tops of the wash-water gutters are 30 in. above the original sand line.

E. G. MANAHAN,† M. AM. SOC. C. E. (by letter).—The details given in this paper regarding the behavior of filter sand and gravel and the losses of head through them when wash-water is applied at various rates of flow are interesting and helpful, and the authors' conclusion to substitute for the wire screen originally put in an additional thickness of gravel is sound. Mr. Manahan.

Although such a screen will probably not be used in the future, further information from the authors as to one of the causes assigned by them for the failure of the screen, namely, corrosion, would be of value. If marked corrosion has occurred in the brass screen during its eight years of service, this fact is important, especially if a like amount of corrosion has taken place in the brass strainer plates. Deterioration of the screen would naturally be expected to result from wear due to the movement of adjacent particles of sand and gravel, rather than from corrosion.

* Cleveland, Ohio.
† Wilmington, Del.

Mr. Manahan.

With the wire screen omitted, the Cincinnati strainer system fulfills satisfactorily all requirements for such a system, except that, with an 8-in. layer of graded gravel, as originally constructed, the velocity of the wash-water as it leaves the orifices in the strainer plates is so high that it may slightly disturb the gravel layer and in time cause mixing of the sand and gravel. This velocity at the ordinary rate used in washing is about 11 ft. per sec., and if this should be reduced to 3 or 4 ft. per sec., it is the writer's opinion that no disturbance whatever of the gravel would take place.

Such a reduction in the velocity through the orifices could have been provided for at an expense no greater than the cost of the screen The cost of the screen and its fastenings was about $0.30 per sq. ft. of net filter area; that of the strainer plates and their fastenings, $0.40; that of placing the screen and plates, $0.33; and that of the concrete ridges in place, $0.20; total, about $1.23. These represent prices paid by the City, and are reasonable, except that the price for placing the screen and plates was too high and that for the concrete was too low.

For the cost of the screen it would have been possible to place a second strainer plate beneath the one used, making both plates, perhaps, a little thinner. The second plate would be of practically the same shape as the first, but placed in an inverted position, with the edges of the two plates in contact and so as to leave a diamond-shaped area between them. Then, by a proper choice of orifices in the plates, the greater part of the loss of head could be made to take place in passing through the lower plate, allowing the water to escape at a comparatively low velocity through numerous orifices in the upper plate. The holes would be arranged so that they would not come opposite one another.

This type of strainer system would give a control of the wash-water more nearly positive than that accomplished by using deep layers of gravel, which latter control is somewhat haphazard. However, the cost of the additional plate, although no greater than that of the screen, would considerably exceed, even at times of normal prices for brass, the cost of the additional gravel; although in a new plant this excess would be reduced to some extent by the cost of the extra depth of filter tank required to accommodate the gravel as well as by the cost of added strength in the filter floor and foundations.

Mr. Willcomb.

GEORGE E. WILLCOMB,* ASSOC. M. AM. SOC. C. E. (by letter).—This paper, presenting a scientific discussion of the many factors relating to the high-velocity wash of a rapid sand filter, is timely and instructive. The literature on the washing of rapid filters is meager. Most of the published reports are based on the individual conclusions of different operators arrived at without any extended research, and,

* Albany, N. Y.

Mr. Willcomb.

from necessity, they contain frequent instances of inaccuracy of interpretation. This paper is especially timely in that it tends to focus attention on the general subject of filter washing at a time when radical action on the question seems imminent. At a recent meeting of a western engineering society, the air-wash as applied to rapid filters was adversely criticized, and a member of the engineering staff of a State Board of Health took the extreme position of recommending that it be abolished in future plants. Such views as these emphasize the importance of research work in connection with filter washing, in order that such a useful adjunct to the washing process as air agitation may not be rejected without good reason. Eastern plants, operating with a water of low turbidity and high in color and sewage contamination, have found the air-wash to be most efficient, and plants constructed 12 years ago are having continued success with this means of agitation. It has been found that most of the troubles have been physical, that is, have been caused by faulty design of the air-wash system.

On the publication of the report of the Commissioners of Water-Works of Cincinnati, in 1909, in which the placing of screens at the junction of the sand and gravel was advocated, many filtration engineers of extended experience in the operation of rapid filters were skeptical as to the benefits to be obtained by the use of such screens at this point. To be sure, the condition brought about by the placing of such screens was almost ideal, for certainly no mixing of the sand with the gravel could result; yet, owing to the stresses that were likely to act on the screen at the beginning and end of a wash, and the likelihood of uneven distribution of the wash-water, all factors seemed to be against any permanency of alignment of the screen.

The ridge-block construction for filter bottoms, though old in principle, has been rapidly developed during the past 5 years, and varying modifications of this type have been incorporated in the design of several plants of recent construction. The advantages of this system are: a smaller volume of gravel is required; unwashed zones in the gravel medium are eliminated; and jet action of the incoming wash-water is prevented. The disadvantages are: increased cost and complication of the construction; the inherent weakness of the design tending toward shearing the anchor-bolts and thus letting sand into the collector channels; and the trouble involved in overhauling the beds during periods of rejuvenation.

As long as a screen for holding down the gravel was used, and only the trapezoidal channels were filled with gravel, there is no doubt that this system assured an even distribution of the wash-water and prevented unwashed zones; but, as soon as the retaining screen was done away with and the gravel layer increased above the tops of the chan-

Mr. Willcomb.

nels, dead spaces were introduced, and practically all the advantages of the system were lost.

From the extended experimentation, the grading of the gravel appears to be of the utmost importance. This paper proves conclusively that the depth and the arrangement of the sizes do not cause a loss of head of more than 0.3 ft. even with a 2-ft. vertical rise. The function of the gravel layer being to support the sand medium, distribute the wash-water, and prevent sand grains from entering the under-drain system, the writer has come to the conclusion that 14 in. of graded gravel, a simple type of sand-valve, and a flat floor, represent optimum conditions, both in regard to economy and good design. That portion of the gravel surrounding the sand-valves should be composed of large units, say from 2 to 3 in. in diameter, and should be at least 4 in. thick. The next layer ranges from 1 to 1½ in., and is 2 in. deep. Next should come a 3-in. layer, ranging from ¾ to ½ in. The next layer is 2½ in. thick, and runs from ½ to ¼ in., followed by a 2½-in. layer of ¼ to $\frac{1}{16}$-in. size. Gravel graded in this manner provides for adequate deflection of the wash-water jet without undue throttling, and allows of a much wider spacing of the sand-valves than is customary. The tendency of the wash-water is to follow up the surfaces of the large gravel units, and conditions are brought about that are quite akin to the mathematical placing of spherical bodies around the valves, a procedure that has been introduced with favorable results quite recently. The main factor to be considered in placing the gravel is the proper sizing of the various layers. Generally speaking, a layer of gravel will remain on top of a lower layer, provided it contains no particles less than one-third the size of the particles on which it rests. The gravel adjoining the sand should not be too coarse in relation to the sand, else mud-balls will tend to be deposited by a too sudden decrease of the velocity during the filtration period proper.

When the Albany experiments in double and rapid filtration were begun in 1905, data were available from the experimental plants at Philadelphia, Cincinnati, and Columbus. At this time the ridge-block under-drain system and high rates of washing were being exploited, and accordingly a small filter with an inverted cone depression at the under-drain was experimented with. A very simple cylindrical sand-valve was developed from seamless brass tubing of No. 20 stock, Stubb's steel wire gauge. The tubes were punched out of one piece with a die, and cost 9 cents apiece to manufacture. The tubes were 4 in. long and had a ⅝-in. bore. There were two rows of staggered holes, ¼ in. down from the top, each being 0.161 in. in diameter. Each hole had an area of 0.02036 sq. in., and the combined area of the eight openings amounted to 0.1629 sq. in., which was 0.2% of the entire filter surface. This was a smaller rate than usual, and gave rise to a friction loss of

head of 3.0 ft. when washing with a vertical rise of 1 ft. The bottom of the tube was made with a flare, and two sets of depressions were sunk into the vertical sides to form a bond when they were concreted into the filter bottom. When the valve was in place in the bed, the holes of the lower set were only ¼ in. above the filter floor, thus preventing the silting up of any portion of the gravel under-drains.

This small filter had a glass side through which the effects of the washing could be observed. The gravel layer consisted of 12 in. of selected pebbles, graduated from 3 in. to ⅛ in., and on this was placed 24 in. of a 0.32-mm. sand having a uniformity coefficient of 2.50. Different rates of washing were used up to 2 ft. rise, and no tendency of the sand to mix with the gravel was noted. On starting the wash, the entire sand body would rise for a distance of from 4 to 6 in., when the bottom particles would begin to detach themselves and take up the motion of the various currents. Great importance was attached to this phenomenon at the time, for it was thought that the violent breaking away of the sand particles would shear the strands of organic matter attached to the sand grains when the large filters were placed in operation, and thus aid materially in the washing process. It soon became apparent, however, that these conditions were not typical, owing to the restricted sand surface of the experimental filter, and that surface tension had a lot to do with the phenomenon, which would not occur in the large beds. The results of these experiments indicated that washes up to 2 ft. rise per min. could be used safely without admixture of the sand and gravel.

When the sixteen large units were built, flat floor bottoms were decided on, as the advantages of the bottom with pyramidal pockets did not justify their additional cost of construction. The results obtained with the experimental filters had demonstrated clearly that the rapid filters, operating as scrubbers without coagulation, would not wash the sand in place in the bed indefinitely, but would have to be given supplemental washes periodically by ejection or other means. As ejection meant removing all the sand down to the gravel, and as this process would be likely to disturb the gravel layer, it was deemed probable that the gravel might have to be regraded at intervals, and that the pryamidal depressions in the floor, in such a case, might interfere with the work.

The sand-valves developed in the experiments were used in the construction of the large beds. These valves were cast in small slabs outside the beds, and, when hardened, were set over trapezoidal ducts formed in the floors of the filters. These ducts ran across the beds and discharged into a main collector of 2 ft. diameter. The main collector and the under-drain ducts acted as a compensator for the wash-water, and insured equal distribution throughout the bed during the

Mr. Willcomb.

wash. The valves were set 9 in. on centers, and were covered with 1 ft. of gravel graded in four lots from 3 in. to $\frac{1}{16}$ in. A depth of 30 in. of silica sand, of 0.45 mm. effective size and a uniformity coefficient of 2.50, was eventually selected for the filter medium. The beds were divided into two parts by the central wash-water gullet which ran the long way of the beds. The wash-water troughs were of rectangular section, 6 in. deep and 10 in. wide (inside dimensions), and were 7.5 ft. apart. One-half of their top opening was closed on the discharge end, so that the maximum travel of any particle of suspended matter was about 4 ft. The crests of the wash-water troughs were placed 10 in. above the normal surface of the sand, and, during the wash, with a 1.5-ft. rise per min., the sand was elevated 6 in.

As long as the sand was new, no difficulty was experienced in washing the beds. At the rate of a 1.5-ft. rise, the entire sand medium was in suspension and agitation, and, after the expenditure of about 3% of the entire yield for wash-water, the beds were washed satisfactorily.

Mr. Willcomb.

chemical work, 100 grammes of the sand were shaken in the sand-engine with 100 c.c. of distilled water for 1 min.; then the whole was diluted to 1 liter, and the different determinations were made on the stock suspension. The newness of the sand is shown by the low percentage of moisture retained on the grains. No organic coats had been formed on the sand at this point, as is also shown clearly by the organic nitrogen and oxygen consumed factors. It is interesting to note the grading of the sand according to the hydraulic values of the grains. As the depth of sampling increases, the effective size increases in like proportion. This grading of the sand is much more marked in the case of a fresh sand than with an old one. There is less friction to the passage of the grains in the former case, and stratification is brought about at the conclusion of the wash. It will be noticed, however, that the uniformity coefficients of the bottom samples are high, denoting the presence of much fine material at the bottom of the bed. It has been found by experience that to accomplish complete stratification according to the hydraulic values of the grain is practically impossible. Convection currents and the liberation of entrained air during the washing process have more or less effect in defeating the attainment of this condition, especially in the case of old sand coated with organic growths.

Mr. Willcomb.

Table 4 shows the condition of the same filter after it had undergone a summer's ripening. The effective size of the sand had been increased by successive scrapings of fine sand from the surface. In considering these data it must be borne in mind that the filter was operating as a scrubber, filtering water which had received 12 hours of plain subsidence. It will be noted that stratification is no longer as pronounced. The organic factors have materially increased, as has the turbidity. A striking feature is the increase in the percentage of moisture, denoting sponge-like action on the part of the sand grains. The efficiency of the wash has materially lessened. In one case, at the bottom section of the bed, there is no efficiency. Everything points to a complete paralysis of the function of the wash. Examined through the microscope, it was observed that the grains were completely coated with brown mossy growths of sewage mould and fungi. Fruiting bodies were in evidence, and the strands of hyphæ were seen bound about several adjacent grains in such a way that the sand was consolidated into clots and mounds. Under such conditions as these, the wash-water would be ineffective at a 2-ft. or a 3-ft. vertical rise. The water, taking the course of least resistance, would pass around these masses of sand without disintegrating them, and, as a consequence, they would sink to the bottom of the bed and form the nucleus of a mud-ball or impervious zone.

Fig. 23 is a diagram of one of the rapid filters, with symbols to represent the condition of the sand. It will be noted that close to the wall the bed is badly silted up from top to bottom; the turbidity of the sand ranges from 2 000 to 3 000. Needless to say, these portions of the bed are inert, and neither filter nor wash. Adjacent to these mud-balls are mounds composed of sand of relatively high effective size and uniformity coefficient. It is at these points that the wash-water, diverted by the mud-balls, finally breaks through, and in so doing, carries much of the coarse gravel from the bottom of the bed to the surface, due to the greater velocity of the wash-water. If this happens in the proximity of a wash-water trough, sand is very likely to be carried into the sewer and lost. It is for this reason that the form or special devices attached to a trough are apt to be ineffectual, in the long run, in preventing the loss of sand. Theoretically, when the wash-water arrives at the point where the troughs are placed, the velocity is increased in direct proportion to the lessening of the superficial area by the surface of the troughs, and some sand is apt to be carried into them and lost. Some designers have attempted to correct this by modifying the shapes of the troughs, and one finds all shapes in use, from semicircular sections to rectangular ones. However, owing to abnormal conditions of the sand and the sudden release of entrained air, the velocity of the wash-water is bound to increase at times, and carry the sand into the trough, regardless of its shape.

Mr. Willcomb.

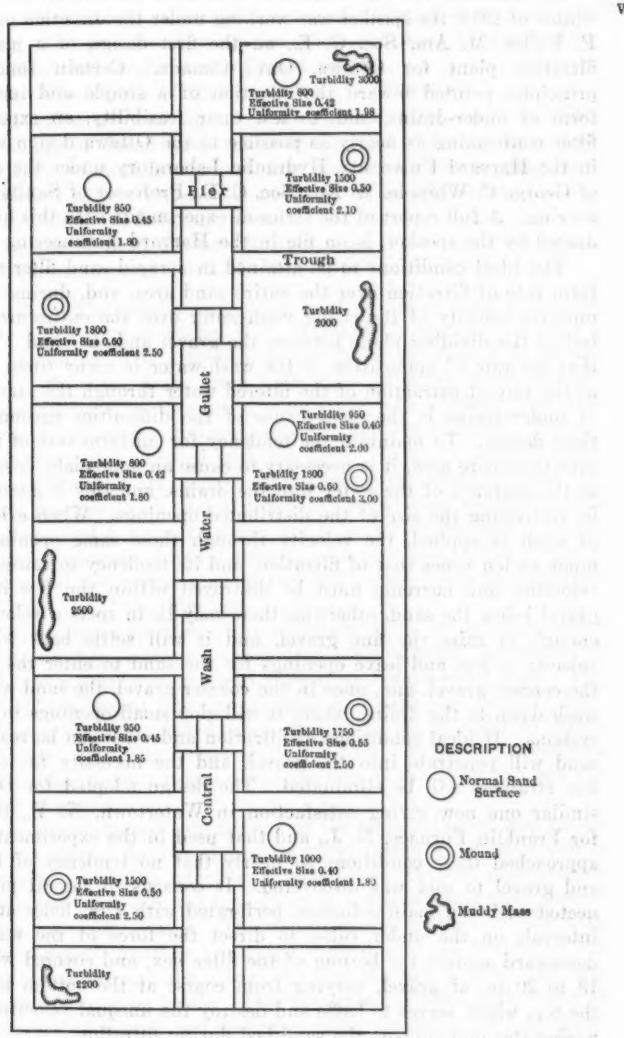

FIG. 23.

Mr. Pirnie.

H. MALCOLM PIRNIE,* JUN. AM. SOC. C. E.†—During the fall and winter of 1913, the speaker was working under the direction of Weston E. Fuller, M. Am. Soc. C. E., on the first design of a mechanical filtration plant for Ottawa, Ont., Canada. Certain fundamental principles pointed toward the adoption of a simple and inexpensive form of under-drains, and, to test their feasibility, an experimental filter conforming as nearly as possible to the Ottawa design was built in the Harvard University Hydraulic Laboratory under the direction of George C. Whipple, M. Am. Soc. C. E., Professor of Sanitary Engineering. A full report of the series of experiments with this filter, conducted by the speaker, is on file in the Harvard Engineering Library.

The ideal conditions to be attained in a rapid sand filter are: uniform rate of filtration over the entire sand area, and, during washing, uniform velocity of the rising wash-water over the entire area of the bed at the dividing plane between the gravel and the sand. The fact that the rate of application of the wash-water is many times as great as the rate of extraction of the filtered water through the same system of under-drains is the chief cause of the difficulties encountered in their design. To maintain the tendency for uniform rate of filtration over the entire area, it is necessary to cause an appreciable loss of head at the entrance of the water into the drains, and this is accomplished by restricting the size of the distributed openings. When a high rate of wash is applied, the velocity through these same openings is as much as ten times that of filtration, and its tendency to cause unequal velocities and currents must be destroyed within the few inches of gravel below the sand, otherwise there may be in spots a velocity high enough to raise the fine gravel, and it will settle back where the velocity is less and leave openings for the sand to enter the voids of the coarser gravel, and, once in the coarser gravel, the sand will easily wash down to the drains, where it will clog small openings in strainer systems. If ideal conditions of filtration and wash can be realized, no sand will penetrate into the gravel, and the necessity for expensive fine strainers will be eliminated. The design adopted for Ottawa, a similar one now giving satisfaction in Watertown, N. Y., that used for Franklin Furnace, N. J., and that used in the experimental filter, approached these conditions so nearly that no tendency of the sand and gravel to mix was discovered. It consists of lateral pipes connected with the main collector, perforated with ¼-in. holes at regular intervals on the under sides, to direct the force of the wash-water downward against the bottom of the filter box, and covered with from 18 to 20 in. of gravel, varying from coarse at the bottom to fine at the top, which serves to baffle and destroy the unequal velocities of the wash-water and support the sand bed during filtration.

---

* Springfield, Mass.

† Now Assoc. M. Am. Soc. C. E.

Mr. Pirnie.

The following is an extract from the report of the tests on the experimental filter. It describes the process of filtration as well as that of washing. One is dependent on the other, and must be observed in order to afford full explanation of what occurs.

Objects.—The objects of these tests were to determine:

1. The effect of washing on a mechanical filter built up with simplified forms and under-drains and different sizes and depths of sand and gravel, first with a water-wash alone, and second with a water-wash preceded by an air-wash;
2. The loss of head during washing;
3. The loss of head during filtration;
4. The intensity and depth of clogging in the sand bed.

Apparatus.—The mechanical filter used in these tests is in the Hydraulic Laboratory at Pierce Hall, Harvard University. As shown in Figs. 24 and 25, it is a wooden box, 2 ft. 11 in. wide, 6 ft. 1½ in. long, and 7 ft. 5 in. deep, fitted with glass windows, a galvanized-iron gutter discharging through a sluice-gate into a waste pipe, and the necessary piping for influent, effluent, and wash-water. An adjustable overflow is connected with the filter. In one side of the box at suitable elevations are placed gauge-cocks with straight tubes for registering positive head, and **U**-tubes for registering negative head. A gauge tube and a pressure gauge are attached to the under-drains. The effluent discharges through a gate and a pipe which is closed by a water seal. All the gauges read in feet and inches below an arbitrary zero set at the top of the filter box.

The under-drains are formed by six lateral 2-in. wrought-iron pipes screwed into a 3-in. collector which discharges through the center of the floor into a 4-in. wrought-iron effluent and wash-water pipe. The free ends of the lateral pipes are capped, and each pipe has five ¼-in. holes in its under side, placed as shown in Fig. 24, in order to direct the wash-water vertically downward to the floor. Between the laterals, and at the sides, wooden ridges direct the flow of the water through the first grade of gravel.

A ¼-in. pipe is tapped into the top of the main collector, and passes through the side of the box through a valve into a **T**, above which is another valve and below which is a waste pipe. A ¼-in. pipe extends from the upper valve into the top of a glass bottle set on a shelf several feet above the under-drains. The mouth of the bottle is closed with a rubber stopper. Another ¼-in. pipe, tapped into the bottom of the collector, passes through the side of the box, through a valve, and into the bottom of the glass bottle. This apparatus is filled with water at the beginning of a test, and indicates when air forms in the under-drains by allowing it to collect in the top of the bottle, water being forced out at the bottom.

Mr. Pirnie.

Both the waste-wash and effluent pipes discharge into a trough below the filter, at one end of which is a weir. This is shown in Fig. 26. The water passing from this weir falls into one or the other of two weighing tanks, according to the way the controlling lever is placed.

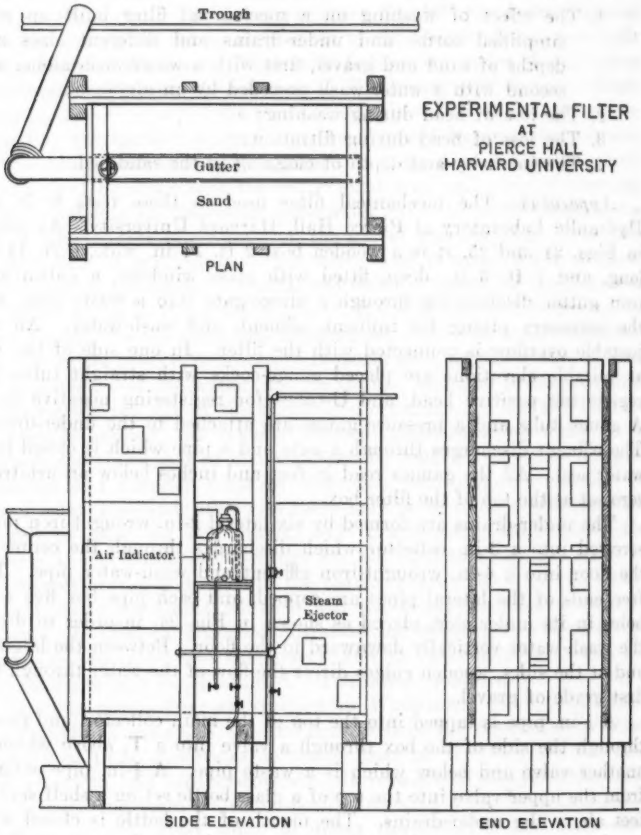

FIG. 24.

By these tanks the rate of wash and effluent discharge can be determined. The waste-valves at the bottoms of the tanks are controlled by levers above the weighing arms, and the discharge through them enters a concrete reservoir of considerable capacity in the sub-basement.

Mr. Pirnie.

A Blake duplex steam pump, Fig. 26, with suction pipes in this reservoir, lifts the water and discharges it into the bottom of an air-tight pressure tank. At a sump in the discharge pipe from the pump to the tank are connected a waste-gate, discharging into the reservoir, and a 4-in. supply pipe for the filter. A ½-in. air line, from the Westinghouse direct-acting air compressor, enters the bottom of the tank through a valve. This arrangement makes possible a pressure service of either air or water. On the supply pipe under the filter are three gates, 2, 4, and 5, as shown in Fig. 26. A 2-in. supply pipe from the city main, with a gate (3), and the 4-in. filter influent pipe, are connected to the supply pipe between Gates 2 and 4. The influent pipe has

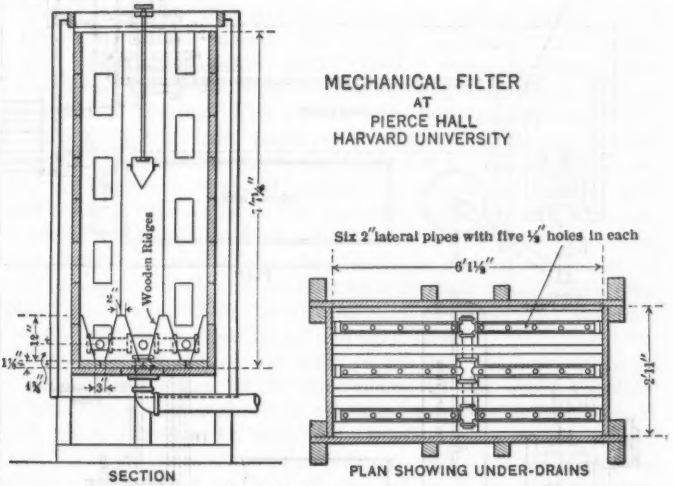

FIG. 25.

a gate (1) above the floor. Between Gates 4 and 5 there is a 4-in. pipe which connects with the effluent pipe between the under-drains and the effluent gates (6). This pipe may be used to carry the wash-water or air to the under-drains, or the effluent to the sewer, as Gate 5 connects the supply pipe with the city sewer. By this system of piping either reservoir or city water can be used for influent or washing purposes.

Four different filter beds were placed and tested. The first two were built above a roughly constructed system of under-drains, and the third and fourth over those shown in Fig. 25.

General Method.—To determine the effect of water-wash on the filter bed, water was forced into the filter through the under-drains at

Mr. Pirnie.

different rates, and was observed through windows in the sides of the filter box. High rates of wash were applied gradually and suddenly, both to clogged and unclogged beds. The effect of air-wash was ob-

ARRANGEMENT
OF PIPING AND APPARATUS FOR
EXPERIMENTAL FILTERS.
AT PIERCE HALL, HARVARD UNIVERSITY.

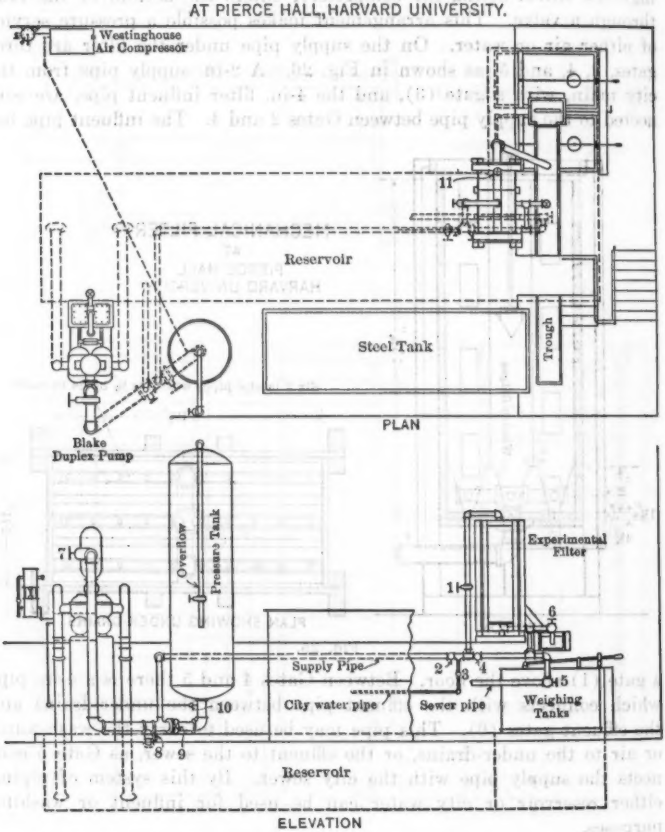

FIG. 26.

served by forcing air through the under-drains into the filter, with the bed clogged and unclogged. Samples of sand, taken at different depths below the surface, were subjected to mechanical analysis, in order to determine the grading effect of the wash.

The loss of head in washing was ascertained by noting the pressures in the under-drains and at different elevations in the filter bed. Mr. Pirnie.

The loss of head during filtration was ascertained by allowing alum-treated water to enter the filter above the sand, flow through the bed, and discharge from the under-drains at determined rates, noting periodically the total loss of head, and the loss of head between different elevations in the bed.

An idea of the intensity and depth of clogging in the sand was obtained from the turbidity of sand samples scraped from the surface and at different depths below the surface of clogged beds. Throughout all the tests watch was kept at the windows in the filter box to observe everything that happened.

First Bed.—In the first strainer system the central laterals were 1 in. lower than the side laterals, their center line being 3.75 in. above the floor. The ridges (of ¾-in. planks nailed to triangular braces) were so uneven that wash-water could enter under them and pass up through large cracks in the top. The laterals were 2-in. wrought-iron pipes, each having six ½-in. holes staggered ½ in. on each side of the lower center line. Over this system, to the depth of 6 in. above the floor, was placed the first grade of gravel, passing a 1.5-mesh and retained on a 1-mesh screen. Practically all this gravel remained above the laterals. The second grade of gravel passed a 1-mesh and was retained on a 3-mesh screen. It was 3.5 in. deep, and was covered with 1 in. of gravel passing a 3-mesh and retained on a 10-mesh screen. The total depth of gravel was 10.5 in. Next came 4 in. of coarse sand, and then 28 in. of a mixture of Plum Island and bank sand.

Second Bed.—A change was made in the first strainer system, all the laterals being placed in the same plane, 4.75 in. above the floor. The same ridges were used. Care was taken to pack the first grade of gravel, which passed a 1.5-mesh and remained on a 1-mesh screen, around five of the laterals, one being left unpacked. The top of the first grade was 5.5 in. above the floor; the second grade (passing a 1-mesh and retained on a 3-mesh screen) was 6.25 in. deep, and the fourth grade (passing a 3-mesh and retained on a 10-mesh screen) was 1.25 in. deep. The total depth of the gravel was 13 in. Over this was placed 3.25 in. of coarse sand and 30.25 in. of Plum Island sand, effective size 0.57 mm. and uniformity coefficient 1.70.

Third Bed.—The strainer system and the ridges previously described (Fig. 24) were placed for this bed, and the largest size of gravel used in the first two beds was discarded. The first grade of gravel (passing a 1-mesh and retained on a 2-mesh screen) was packed carefully about the laterals, and enough was used to cover the ridges, bringing the surface to 12.5 in. above the floor. The second grade (passing a 2-mesh and retained on a 3-mesh screen) was 3 in. deep; the third (passing a 3-mesh and retained on an 8-mesh screen) was

Mr. Pirnie. 2 in. deep; and the fourth (passing an 8-mesh and retained on a 10-mesh screen) was 1 in. deep, making the total depth of gravel 18.5 in. Above this was placed 21 in. of Plum Island sand, the effective size of which was 0.57 mm. and the uniformity coefficient 1.70.

Fourth Bed.—The sand of the third bed was removed, and 23¾ in. of white Ipswich beach sand was substituted, having an effective size of 0.37 mm., and a uniformity coefficient of 1.65. The gravel and underdrains were the same as those for the third bed.

Details of Experiments.

The loss of head was determined at different periods during the run by reading all the gauges, and the rate was ascertained by weighing the effluent. When the head became negative at any one gauge, the positive-head gauge was shut off, and the negative-head gauge at the same elevation in the bed was turned on. A careful watch was kept on the sand bed through the windows and on the air indicator. In removing the sand beds, care was taken not to disturb the conditions at the surface of the gravel, and, when within a few inches of the gravel, the sand was scraped off carefully so that its condition in the parts of the bed away from the windows could be seen.

In replacing the filter bed, each grade of gravel was carefully leveled before the next grade was placed, and, when the last grade had been smoothed off, the filter was filled with water up to the gutter. The sand was dumped into the water, and settled on the gravel in piles, after which the wash was turned on, causing the bed to come to a uniform level.

First Bed.—On the speaker's arrival in Cambridge, February 3d, 1913, the first bed had already been placed. It was in poor condition, as the sand was mixed with the gravel. When the filter was running, sand escaped continuously from the effluent pipe. The bed was in such poor condition that no quantitative tests were made, but a few preliminary observations were taken in order to test out various parts of the apparatus. The filter was run at the rate of 125 000 000 gal. per acre per day, with alum applied to the influent, and the bed was watched through the windows. After running several hours, conditions of negative head were established, and the sand began to dry out about 6 in. below the surface, the latter being very dirty and covered with a slimy coat of alum flock. The sand was discolored from 3 to 4 in., varying from a marked stain at the surface to no noticeable color 4 in. below. The drying out in the sand increased, and the rate of filtration decreased rapidly. On closing the effluent gate suddenly air began to escape on the surface of the bed, giving an appearance like the start of an air-wash.

In a clogged condition the bed was washed with water applied suddenly at a rate of 2.6 ft. per min. The imprisoned air escaped first

at several points near the sides of the box, and then from the surface of the sand. Then 6 in. of the bed rose in a mass, hit the bottom of the gutter, and broke. Marked streams of greatly agitated sand shot up through a bed of less agitated sand. These streams waved slightly in their upward course, but the points in the gravel where they originated were fixed, showing that the wash-water had a much greater velocity at these points than at others. Some of these streams were swifter than others, and when they reached the top of the sand it seemed to boil. The sand between the streams had a downward motion, and was caught at the gravel and shot upward in the currents. The velocity of wash was noticeably greater at the sides and ends of the box than in the middle. Mr. Pirnie.

After washing, the water was drawn from the filter and the surface inspected. About the ends and sides of the filter there were clearly marked spots of coarse sand which were 5 or 10 sq. in. in area and formed the tops of shafts of coarse sand extending vertically to the gravel. These shafts had been formed at places in the bed where there was higher velocity of wash-water. After experimenting with this bed long enough to obtain a clear idea of its imperfections, it was taken out.

Second Bed.—After the gravel and 3.25 in. of coarse sand had been put in place, a wash of 2.5 ft. per min. was turned on. The agitation seemed to be greater at the ends of the box than in the main part of the bed. The greatest agitation was over the lateral which had been left unpacked in setting up the bed. When all the sand was placed in the bed and the wash was turned on, a very pronounced stream of swiftly moving sand extended upward from the top of the gravel directly over the unpacked lateral. It was accompanied by a violent boiling at the surface. There were other streams which were not so marked, and between them the sand descended slowly, only to be caught and shot up again by the currents. The streams over the packed laterals seemed to be very uniform in upward velocity, and their courses shifted back and forth on the way to the surface. On the whole, the wash was more uniform than in the first bed, but did not appear to be uniform enough to insure against the mixing of sand with the gravel.

After the wash the filter was drained and the surface of the bed examined. The central part presented a smooth surface of fine sand, but, close to the sides, there were several small patches and one large one of coarse sand near the end over the unpacked lateral. These spots occurred wherever the velocity of the wash-water was greatest.

An explanation of what is meant by the term "negative head" will make its use clearer. A filter in operation has a given head of water above the sand bed and is discharging water through its under-drains at a given rate. As the water passes through the filter bed into the under-drains there is a loss of head due to eddies and frictional re-

Mr. Pirnie.

sistance which is equal to the difference between the head as registered on the top of the sand and that in the under-drains. Now, if the top few inches of the sand are clogged so that more head than that available above the surface is necessary to force water through at the given rate, the additional head is obtained from water below the clogged part of the bed, that is, the water below pulls on that above just enough to force it through the clogged portion at the given rate. In general, when the loss of head in passing the sand at a given point in the bed exceeds the head of water above that point, a suction exists equal to the difference between the total loss of head and the head available above that point. This suction is called the negative head at the point in question.

The dot and dash line cutting two of the curves (Fig. 27) gives for any point in the sand bed the total head of water above that point; hence, at any point, if the plotted loss of head falls to the right of this line the head is negative by the amount it falls to the right, and, if it falls to the left, the head is positive by the amount it falls to the left. As the loss of head in the lower part of the filter bed is constant for constant rates, and is only a fraction of the difference in elevation between the top and bottom of this part of the bed, some of this head may be used in pulling water through the top of the sand and still leave a positive head on the under-drains. Thus, a considerable negative head may exist just under the surface of the sand, though the head is still positive on the under-drains. Negative head in a filter is always at its maximum just under the clogged surface of the sand, and this is where air first begins to free itself from the passing water and fill the sand voids.

Water subjected to reduced pressure gives up air, which at first collects in little pockets in the sand voids. The surface coating of the sand, under the increasing pressure, breaks through in places from time to time, suddenly compressing an air pocket which breaks the surface in another place and escapes. Some flock is carried through the breaks, and forms another coating deeper in the bed. This action continues until the clogged portion of the sand is too strong to be broken, and then air accumulates in the sand voids until a cushion of air is formed between the clogged surface sand and the reservoir of water supplying the under-drains. As soon as this happens, the hydraulic unity of the filter is destroyed, and two separate actions begin, namely, the discharge of water above the sand through the clogged surface into rarified air, and the discharge from a body of water under a partial vacuum through the effluent-gate into water under atmospheric pressure. Air continues to escape from the water that passes through the surface of the sand, and, expanding, reduces the available negative head by replacing with air part of the head on the under-drains. The discharge of water through the clogged surface

decreases rapidly as the available negative head is reduced, and soon all the water in the lower part of the bed is discharged, leaving the bed filled with air and supporting above its clogged surface a reservoir of water. This rapid reduction in available negative head was due to the fact that the filter box was not absolutely tight, and air leaking in quickly reduced the vacuum when the head became negative in the vicinity of a leak. It is very important, therefore, to have a filter absolutely tight, if it is to be operated under negative head. The reduction of available negative head was much more rapid in the experimental filter than it would be in a tight concrete unit. Mr. Pirnie.

CURVES FOR LOSS OF HEAD TEST
FROM TABLE 5.
FEBRUARY 25TH, 1913.
Distribution of Loss at Different Periods during Run.

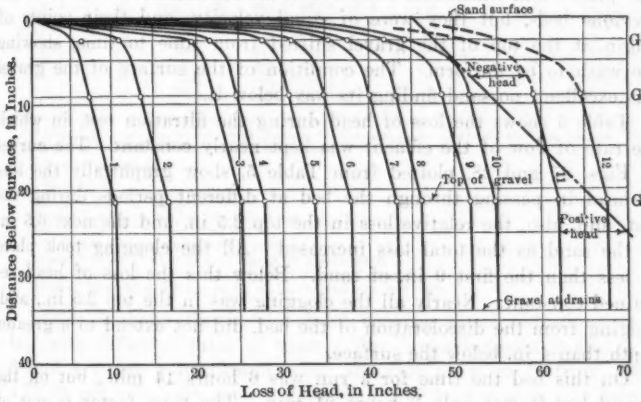

FIG. 27.

The curves showing the comparative losses of head in the top of the sand explain themselves. By far the greatest loss is in the top 1½ in. of sand, and the rest of the variable loss takes place in less than the next 11½ in. The loss below Gauge 3 remained constant throughout the run.

An air-wash was applied to the filter in this clogged condition. The surface was completely broken up, and the dirt and top sand shot up into the water standing a little below the level of the gutter. Water penetrated only 4 or 5 in. into the bed, as the rising air kept it out of the lower portion, and therefore there was no disturbance between the sand and gravel. At the end of the air-wash the water above the sand was black with flock, and the surface was in mounds and valleys. The application of a water-wash cleared away all the dirt, and at the end left the bed smooth and clean.

Mr. Pirnie.

Throughout the experiments with the second bed, no sand escaped from the effluent pipe, and, on taking out the bed, it was found to be in very good condition. In a few places, however, sand was mixed with the fine grade of gravel, and this was very markedly the case over the unpacked lateral near the end of the filter.

Third Bed.—After the gravel had been put in place, a wash of 2.5 ft. per min. was turned on. The water was clear enough to allow inspection of the surface of the fine gravel for a considerable distance back from the windows, and it was seen to be very uniformly agitated. There was no fixed point of boiling, thus showing the velocity of wash to be uniform throughout the main part of the bed. The agitation at the ends, however, appeared to be slightly greater. The sand was placed and washed at the same rate. Streams existed, as in the previous beds, but they were of equal velocity, and their points of origin at the top of the gravel shifted from time to time, showing the wash to be uniform. The condition of the surface of the gravel was excellent, no sand finding its way below it.

Table 5 shows the loss of head during the filtration test, in which the rate of flow of the effluent was kept nearly constant. The curves of Figs. 27 and 28, plotted from Table 5, show graphically the loss of head in passing through the bed at different periods during the test, and, also, the relative loss in the top 2.5 in. and the next 6.5 in. of the sand as the total loss increased. All the clogging took place in less than the first 9 in. of sand. Below this the loss of head remained constant. Nearly all the clogging was in the top 2.5 in., and, judging from the discoloration of the bed, did not extend to a greater depth than 4 in. below the surface.

On this bed the time for a run was 6 hours 14 min., but on the second bed it was only 3 hours 21 min. The time factor is not of much use, as an unknown quantity of alum was applied to the influent, which varied in alkalinity; but it is obvious that, the longer the occurrence of negative head can be postponed, the longer the filter will run, and this was accomplished in the tests on the third bed by having a greater head of water above the sand than was available on the second bed. Near the end of the test the same conditions existed as in the tests on the second bed.

A sudden high rate of wash was turned on the bed after it was thoroughly clogged. The imprisoned air was compressed until it lifted and broke the surface, causing conditions similar to the start of an air-wash. Water rose through the gravel, lifted the sand in places, and then produced the condition of streams, previously described. No mixing of the sand and gravel was caused by the sudden application of the wash.

*There was no negative-head gauge at Gauge 2, so that when this gauge became negative the losses between 1 and 3 were read.

†2 and 3 negative.

‡4 negative.

Gauge 5 was out of order.
Gauge 2 is 2¼ in. under sand surface.
Gauge 3 is 9 in. under sand surface.
Gauge 4 is 21¼ in. under sand surface.
Gauge 6 connected with effluent pipe above gate.
Gauge 4 is ⅝ in. below top of fourth grade of gravel.
Loss of head in gravel = ¼ in. at 125 000 000 gal. per day.

Table 6 shows the loss of head between given elevations in the bed with different rates of wash. The losses between 2 and 3 and 3 and 4 reach a maximum when the rate of wash is from 1.43 to 1.77 ft. per min. At rates higher than 1.77 ft. per min., the losses of head decreased. Between Gauges 4 and 5 in the gravel, the loss of head increases steadily with the increase in rate of wash, which is true also between Gauges 5 and 6, as the water passes from the under-drains into the gravel. The perforations in the under-drains, as well as the voids in the gravel, remain constant during the wash. Therefore, as the velocity of wash increases, the losses of head in the under-drains and the gravel increase. It is different with the sand, however. The upward current of water exerts a frictional force on a sand grain, its intensity depending on the velocity of the water and the size and shape of the grain, and when this force exceeds the weight of the grain in water, it is carried up until a position is reached where the velocity, and therefore the frictional force, is less. Thus the finest grains of sand find their way to the top and become suspended in the rising column of wash-water just near enough together to cause the velocity required to keep them in their suspended positions.

Mr. Pirnie. As the rate of wash is increased, heavier particles become suspended below the lighter ones, and the total voids in the sand are correspondingly increased. A measurement of the increase in voids may be obtained by multiplying the area of the filter by the distance the sand surface is raised. When the sand particles are suspended, there can be no greater scrubbing action caused by a higher rate of wash. The voids simply increase in size, allowing the velocity of the water passing the sand grains to remain the same. Therefore, for this sand, the maximum useful wash rate would seem to be 1.77 ft. per min. Greater rates increase the voids and do not increase the scrubbing action on the particles.

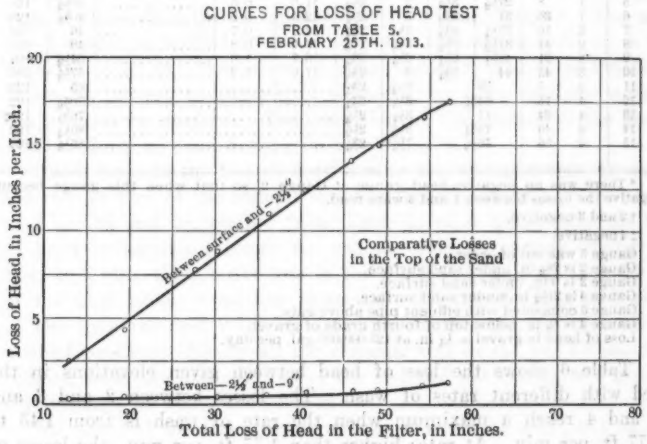

FIG. 28.

At the end of the test, little lumps of sand, held together by some binding material, settled back on the surface. These were not present after an air-wash, but they are not broken up by a water-wash. They are suspended out of reach of the stirring action, and settle back unbroken on the surface after the wash. These masses reduce the clear surface of the bed. This may be desirable, inasmuch as it helps to form more quickly the desired filtering surface. If it is undesirable, the best way to break up these masses is with an air-wash.

Fig. 29 shows the grading of the sand in the third bed, due to washing. It is interesting as a proof of the way the sand is suspended by the upward current of water. On turning off the wash, the sand settles according to its size, the larger particles settling out first, and the smaller ones being deposited in successive layers

on the coarser ones below them. The wash tends to make a mechanical separation of the entire bed of sand, and, because the sand curve is a straight line on a multiple logarithmic scale, in the natural sand, it is graded in the same way in a mechanical filter. The uniformity coefficient approaches unity at the surface, but, owing to foreign matter and irregularly shaped particles of sand, it is not unity. Deeper in the bed the stirring action of the streams mixes some larger particles with the sand, so that the uniformity coefficient is increased. Mr. Pirnie.

Pressure gauge has zero correction of + 1.5 lb. per sq. in., which has been applied in this table.
Gauge reading at under-drains = 84.5 in.
Gauge 5 is in gravel at drains 1¾ in. above center line.
Gauge 4 is in gravel 5⅝ in. below top.
Gauge 3 is in sand 11⅝ in. above gravel.
Gauge 2 is in sand 18½ in. above gravel.
Gauge 1 is above sand.

Fig. 30 gives a good indication of the depth and intensity of clogging in the third bed. From inspection of the bed after clogging it was apparent that the surface sand was discolored to a depth of 4 in., varying from a very marked discoloration at the surface to no noticeable color deeper than 4 in. below the surface. Comparing the turbidity curve of samples scraped from a washed bed with that curve for samples scraped from a clogged bed, it can be seen that the dirt does not penetrate below the upper 5 or 6 in. of the bed. This method does not give an accurate record of the intensity of clogging at different depths. Some of the dirt was in lumps, or adhered to the sand particles after drying, and therefore did not add to the turbidity of the water with which the sample was shaken. The curves, however, indicate clearly the way in which the clogging was distributed.

An air-wash was applied to the bed in an unclogged condition. At the start the bed was full of water, and the rising bubbles thoroughly mixed the sand and finest gravel. Almost instantly, however, the

Mr. Pirnie.

water was driven out of the fine gravel and sand by the rising air, causing all disturbances to cease except those at the surface of the sand. At the start the air pressure in the under-drains was 2 lb. per sq. in., and this was reduced to 1.5 lb. per sq. in. when the water was forced out of the sand. As the water stood at the level of the gutter when the wash was started, an overflow occurred, and carried with it a considerable quantity of sand. This was thoroughly mixed with the water, owing to the violent stirring action of the air bubbles. The overflow ceased as soon as the water had been expelled from the bed. This waste of sand could be avoided by drawing the water below the level of the gutter before starting an air-wash on an unclogged bed. It would not be necessary on a thoroughly clogged bed filled with air.

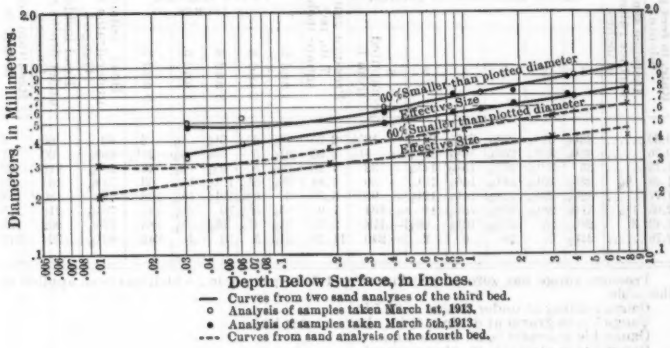

FIG. 29.

After the air-wash, a high-velocity water-wash was applied, driving the sand out of the fine gravel and leaving the bed in as good condition as it was before the test. The little masses of sand which existed after a water-wash alone were not present after this test, showing that an air-wash preceding a water-wash is the more thorough method of cleaning the sand.

When the sand of the third bed was removed, the gravel everywhere was found to be in the same condition as when placed. No sand was mixed with it. In view of the fact that all possible variations of washing were used without producing permanent bad effects, this form of bed was considered satisfactory.

Fourth Bed.—When the Ipswich Beach sand had been placed in the filter, a water-wash was applied to grade it out. The desired effect was produced in this bed with a considerably lower rate of wash than was necessary to produce the same effect on the third bed. A few shells and some gravel separated from the sand, and formed on top of

the gravel originally in the filter. The sand was graded according to size above it. Mr. Pirnie.

All the clogging took place in less than the upper 5.25 in. and most of it took place in the upper 0.5 in. Negative head occurred in the same way, and with the same effect as in the other three beds. The run was of much shorter duration, owing to the fineness of the sand used. The discoloration in the sand extended from $\frac{1}{2}$ to $\frac{3}{4}$ in. below the surface, giving a visible measurement of the depth of clogging. This was about one-sixth as great as the depth of clogging in the third bed.

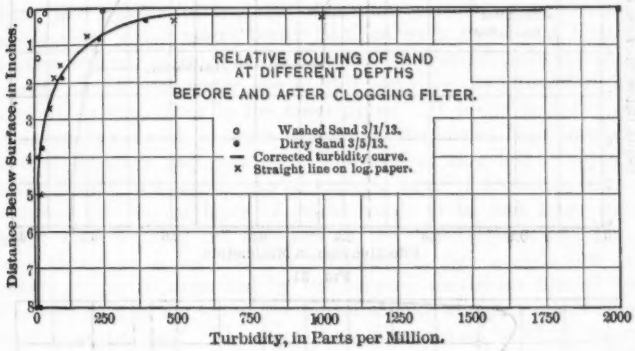

FIG. 30.

The top 8 in. of sand was suspended with a wash rate of 1.15 ft. per min., a condition which was not produced on the third bed until a wash rate of more than 2.5 ft. per min. was used. As described under the third bed, greater rates of wash than that necessary to suspend the sand produced little additional cleansing action. Therefore, for the sand used in the fourth bed a maximum rate of 1 ft. per min. would seem to be more than ample.

A high-velocity wash applied suddenly to this bed lifted it bodily from the gravel before it broke up and began the stream action in the sand. No sudden washes with air or water seemed to affect seriously the condition of the boundary between the sand and gravel. The air-wash applied to the unclogged bed produced the most serious results. These were apparently remedied by the application of the high-velocity water-wash.

Fig. 29 demonstrates the grading of sand in the fourth bed due to washing. By comparing the curves a good idea may be had of the relative sizes of the sand in the third and fourth beds.

Figs. 31 and 32 show the effect of washing on sand placed in a mechanical filter. When the sand is first placed in the filter the effec-

Mr. Pirnie.

tive size and uniformity coefficient are the same at all elevations in the bed. The wash causes a mechanical separation of the different sizes. The finest grains are forced to the surface, and the larger ones are adjusted in layers below the surface according to size.

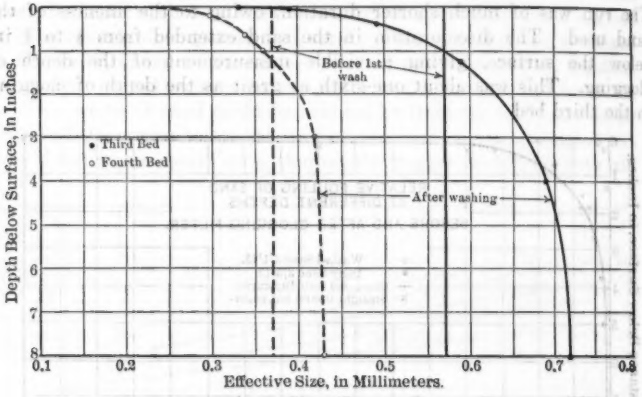

FIG. 31.

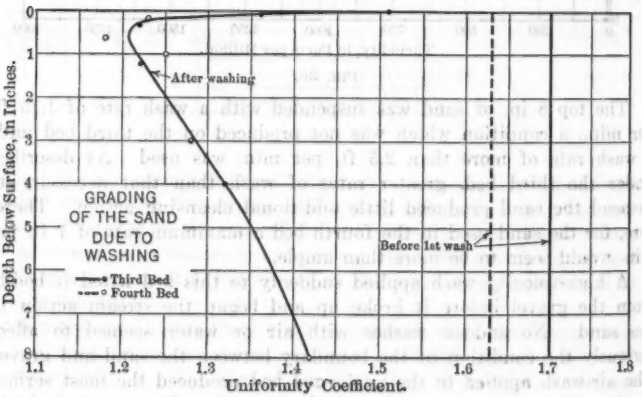

FIG. 32.

Conclusions.—If a filter can be constructed so that the wash-water has a uniform velocity when it passes from the gravel into the sand, there will be no tendency of the gravel and sand to mix. This condition was so nearly attained in the third and fourth beds that the sand remained above the gravel after very high rates of wash had been suddenly applied and shut off. The tendency toward a slightly

greater velocity of wash at the ends of the filter than in the main part of the bed was probably caused largely by the smoothness of the walls. The gravel between the ridges conducted the water with little loss of head to the ends, where there was less resistance afforded by the sand against the smooth filter walls than by the sand in other portions of the bed. There is no reason for building ridges parallel to the under-drains and not perpendicular to them. The tendency toward unequal velocities in one direction is as great as in another. Thus, if ridges are to serve their purpose completely, they should be constructed in the form of concentric rectangles about the center of the filter. The speaker believes that ridges are worse than useless. They occupy space which might better be filled with gravel and thus give a larger reservoir of voids at the bottom. This would make the upward velocity of the wash-water less at this elevation, and therefore allow a greater baffling effect in the lower gravel. It would be better, also, to use smaller gravel, in order to increase the loss of head through it, both in filtration and washing. The greater this loss of head the nearer are the ideal conditions of uniform rates of filtration and wash realized. The lowest layer of gravel needs to be just large enough not to enter or plug the openings in the under-drains, and the top layer should be a considerable thickness of fine gravel, just large enough not to be disturbed by the adopted maximum rate of wash. The sand next to the top of the gravel should be only slightly smaller than the gravel itself. The sides of the filter should be rough, in order to increase the friction and remove the possibility of unequal velocities of wash. Mr. Pirnie.

The strainer system, Fig. 25, is excellent, and, if covered with from 18 to 24 in. of gravel ranging in sizes from coarse at the bottom to fine at the top, should produce a uniform velocity of wash through the sand.

Water-wash, when the rate is high enough to suspend the sand grains, grades the sand according to size. The finest sand is on the top, and the successive lower layers are each coarser than those above.

The wash tests on the third and fourth beds indicate that, for sands of different effective sizes, there are different effective rates of wash. Higher rates give little or no additional scrubbing effect, but may be high enough to carry away the lumps which are formed in some filters.

Air-wash is necessary to break up lumps that form on the surface of the sand. A very high-velocity water-wash will not do this, although, if high enough, it will get rid of some of the lumps by washing them into the gutters. If the sand and gravel are filled with air before an air-wash is applied, no disturbance is caused, except in the top few inches of the sand, and this produces no mixing of the sand and gravel. If, however, the bed is filled with water at the start of the air-wash, the rising bubbles cause violent eddies which mix the fine

Mr. Pirnie.

gravel and sand to an alarming extent before the water is driven out. The high-velocity water-wash regrades the sand and fine gravel, and therefore no permanent injury is done by the air-wash; but it is necessary to have a 3 or 4-in. thickness of fine gravel to make sure that no sand reaches the coarser gravel, and it is also necessary to follow an air-wash with a high-velocity water-wash to expel from the gravel the sand that has penetrated into it. A low-velocity water-wash will not force the sand out of the gravel, and, if an air-wash is continuously used on a filter, followed by a low-velocity water-wash, this sand may work its way down to the under-drains.

During filtration, all the loss of head due to clogging takes place in the top few inches of the sand. Therefore, negative head first occurs just under the clogged surface, and may exist there while the head is still positive on the under-drains. The maximum negative head is always just under the clogged surface of the sand. Therefore, air first begins to be freed from the water and to collect there. The water entering the under-drains has previously been subjected to a higher vacuum than can exist at the under-drains, and therefore should not release air when passing into them. Air that forms under the clogged surface reduces the available negative head by reducing the depth of the reservoir of water supplying the under-drains. A very small leak in the filter walls will supply air in larger quantities under the clogged surface, and therefore reduce the available negative head more rapidly. There is also an element of danger in operating under negative head if air leaks occur below the surface of the gravel. A procession of bubbles will begin to rise through the gravel and sand, collecting under the clogged surface, as soon as the head becomes negative at the leak. This will cause the same mixing between the gravel and sand as that which takes place at the start of an air-wash, and the mixing will continue. The water passing downward in the process of filtration will help to carry the sand down into the coarser gravel, where it will remain when the filter is washed. Each time, toward the end of a run, the disturbance will occur at the same place, and, in this way, a considerable quantity of sand may pass through the gravel to the under-drains. Therefore, it is much better to increase the head above the sand than to try to operate under a large negative head.

The depth of the sand is an important consideration in the design of mechanical filters. Every unnecessary inch of depth means the sacrifice of positive head equal to 1 in. plus the loss of head in passing through 1 in. of the unclogged portion of the sand. If a very uniform rate of filtration can be realized, it may be that the depth of sand can safely be reduced. Filtration at such a high rate is almost, if not entirely, a straining process. Therefore, very little benefit could

be expected from longer contact with sand after the water has passed through the finest straining layers. In the coarsest sand used in these tests the depth of clogging was only 6 in. This indicates that a depth of sand of from 12 to 18 in. would be ample. Mr. Pirnie.

The results of the experiments left no doubt of the desirability of producing a uniform rate of wash over the entire bed. It is obvious that this may be brought about in much less space by directing the wash-water downward as it leaves the under-drains, thus breaking up the force of the individual streams against the solid filter floor. Sufficient gravel may be placed over the drains to quiet the eddies and currents remaining after the force of the streams has been broken. This depth may be much less than would be necessary if the wash-water streams were directed upward. In this case the gravel must break up the velocity of the streams as well as still the eddies and currents caused by them.

JOHN H. GREGORY,* M. AM. SOC. C. E.—The authors, as well as several of those who have discussed the paper, have presented data of especial value to engineers and others having to do with the design, construction, and operation of rapid sand filter plants. Had this information been available 15 years ago, when the present type of rapid sand filter was first being worked out, the task of the engineer engaged in designing such filters would have been greatly simplified. Mr. Gregory.

With reference to the head required to wash filters, it should be noted that the experiments record the head necessary to pass the wash-water up through clean sand. The paper and discussion would be of still greater value if data could also be included showing what increased head, if any, is required to wash dirty filter sand, that is, sand in which the interstices have become clogged with dirt and other foreign matter in the actual process of filtration.

F. A. BARBOUR,† M. AM. SOC. C. E.—This paper is of particular value to those interested in the design and operation of rapid sand filters. It makes available information of which but little has previously been made public, and which will prove valuable in future work, if used with due regard to the relation between the experimental conditions on which the data are based and those of practical operation. Mr. Barbour.

In connection with the building of the filter plant at Akron, Ohio, an investigation of the effects of high-rate filter washes, similar to that described in the paper, was carried out, at the suggestion of the writer, by the New York Continental Jewell Filtration Company—the contractor on that work.

In the Akron filters, the Wheeler filter bottom was used, the right being granted, without payment of royalty by William Wheeler, M.

* New York City.
† Boston, Mass.

Mr. Barbour.

Am. Soc. C. E., the designer and patentee. This filter floor consists of pyramidal depressions, 5.5 in. deep and 8.8 in. across the base, with a $\frac{3}{4}$-in. brass tube, 1.49 in. long, set at the apex, for the discharge of the filtered water or the admission of wash-water from the lateral channels or collectors below. The dimensions of the pyramidal depressions are such that five cement balls, 3 in. in diameter, one at the center at the apex of the $\frac{3}{4}$-in. opening, and four others in an upper layer, are in contact with each other and with the sides of the inverted pyramid. In the spaces between the upper four balls, nine marbles, each $1\frac{1}{4}$ in. in diameter, are laid, and on this a 6-in. layer of gravel is placed. Two views of this filter floor are presented, Fig. 33 showing several of the depressions, one empty and the others with one or more of the balls in place, and Fig. 34 showing a portion of the completed floor in one of the Akron filters.

The type of filter bottom just described has merit in low first cost, in freedom from dead spaces, and in the absence of metal parts subject to depreciation; but the most interesting feature is the complete distribution of high wash-water flows by the balls and marbles, so that with rates of wash up to and exceeding 4 ft. per min., there is no perceptible movement of a 6-in. gravel layer, even before the sand is placed, and therefore no need of any wire cloth, such as was used originally in the plant at Cincinnati.

A small filter with a floor of this type had been constructed at Belfast, Me., previous to the Akron work, and R. S. Weston, M. Am. Soc. C. E., had demonstrated the possibilities of high-rate washes in an experimental filter. The contractor for the filter equipment at Akron, however, had no previous knowledge of this type of floor, and, at the suggestion of the writer, a small experimental filter, 2 ft. square, with a standard Wheeler floor of four depressions, overlaid by 6 in. of gravel and 30 in. of sand, with plate glass on two sides, was constructed. This was used in various studies of the loss of head, at different rates of wash, of the gradation in the sand grains resulting from high-rate washes, and of the relation between the rates of wash and the expansion and rise of sand.

The gravel consisted of three layers, the lowest $1\frac{1}{2}$ in. thick, of material passing a $\frac{3}{4}$-in. and held on $\frac{1}{2}$-in. mesh; the intermediate, $1\frac{1}{2}$ in. thick, of material passing a $\frac{1}{2}$-in. and held on a $\frac{3}{16}$-in. screen; and the top 3 in. of material passing a $\frac{3}{16}$-in. screen and held by a screen with 12 meshes per inch. The sand had an effective size of 0.40 mm. and a coefficient of uniformity of 1.60. The loss of head was determined by glass water columns.

Four curves are presented on Fig. 35, which show the loss of head under four conditions: through the $\frac{3}{4}$-in. opening and pyramidal depression without the balls in place, with the center ball in place, and

Mr. Barbour.

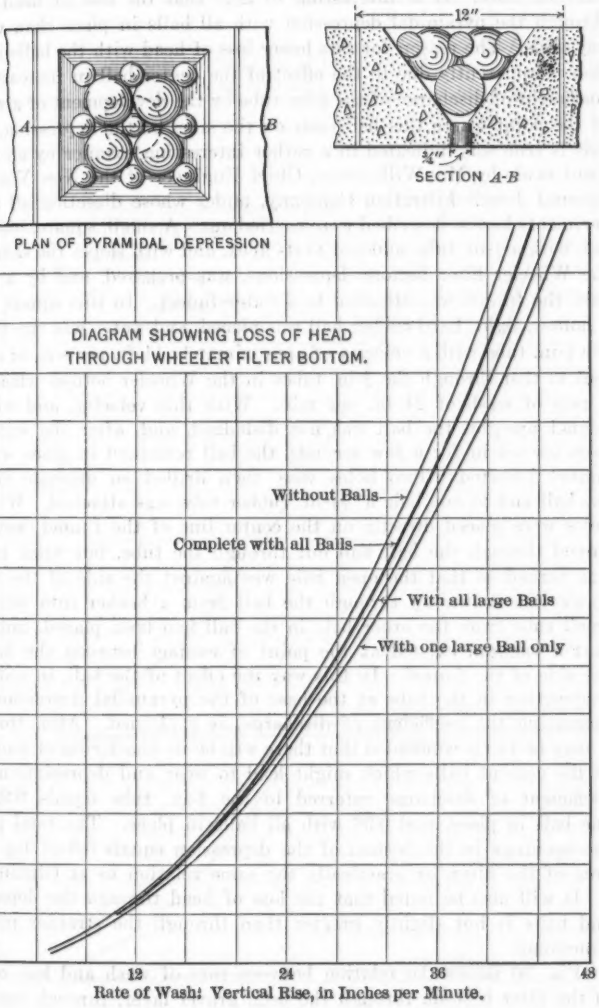

FIG. 35.

Mr. Barbour.

with the five 3-in. balls in place, and the five 3-in. and nine 1¼-in. balls in place. It is interesting to note that the loss of head is less through the pyramidal depression with all balls in place than without any balls. The reason for this lesser loss of head with the balls in position is apparently due to the effect of the center ball in increasing the coefficient of discharge of the ¾-in. tube by the development of a vacuum at the point where this ball rests on the sides of the depression. That this is true was indicated in a rather interesting manner by an experiment made by Mr. Williamson, Chief Engineer of the New York Continental Jewell Filtration Company, under whose direction all the experiments herein described were carried out. A small, square, brass funnel, with a ¼-in. tube soldered to its apex, and with slopes the same as in the Wheeler filter bottom depressions, was prepared, and by a rubber tube the funnel was attached to a water faucet. In this square funnel a hollow, light, hard-rubber ball was placed, and water was run through the ¼-in. tube with a velocity of approximately 11 ft. per sec., or equivalent to that through the ¾-in. tubes in the Wheeler bottom when using a rate of wash of 24 in. per min. With this velocity, and with the funnel upright, the ball was not dislodged, and, after the water had been turned in for a few seconds, the ball remained in place with the funnel inverted. Two holes were then drilled on opposite sides of the ball and to one hole a $\frac{1}{16}$-in. rubber tube was attached. When the holes were placed directly on the center line of the funnel, water was forced through the ball and out through the tube, but when the ball was turned so that the open hole was against the side of the funnel, water was drawn up through the ball from a beaker into which the small tube from the other hole in the ball had been placed, indicating that a vacuum existed at the point of contact between the ball and the side of the funnel. In this way the effect of the ball, in nullifying contraction in the tube at the base of the pyramidal depression, thus increasing the coefficient of discharge, is explained. Also, from this it may be fairly concluded that there will be no chattering or movement of the cement balls which might lead to wear and depreciation. The coefficient of discharge referred to the ¾-in. tube equals 0.92 with one ball in place, and 0.90 with all balls in place. The total area of the openings in the bottom of the depression equals 0.3 of 1% of the area of the filter, or practically the same relation as at Cincinnati.

It will also be noted that the loss of head through the depressions and balls is but slightly greater than through the strainer plates at Cincinnati.

Fig. 36 shows the relation between rate of wash and loss of head in the filter bottom, through the 6-in. gravel layer, through the 30-in. layer of sand, and through the complete filter. The rate of wash in the experiments ranged from 10 to 42 in. per min. It will be noted

Mr. Barbour.

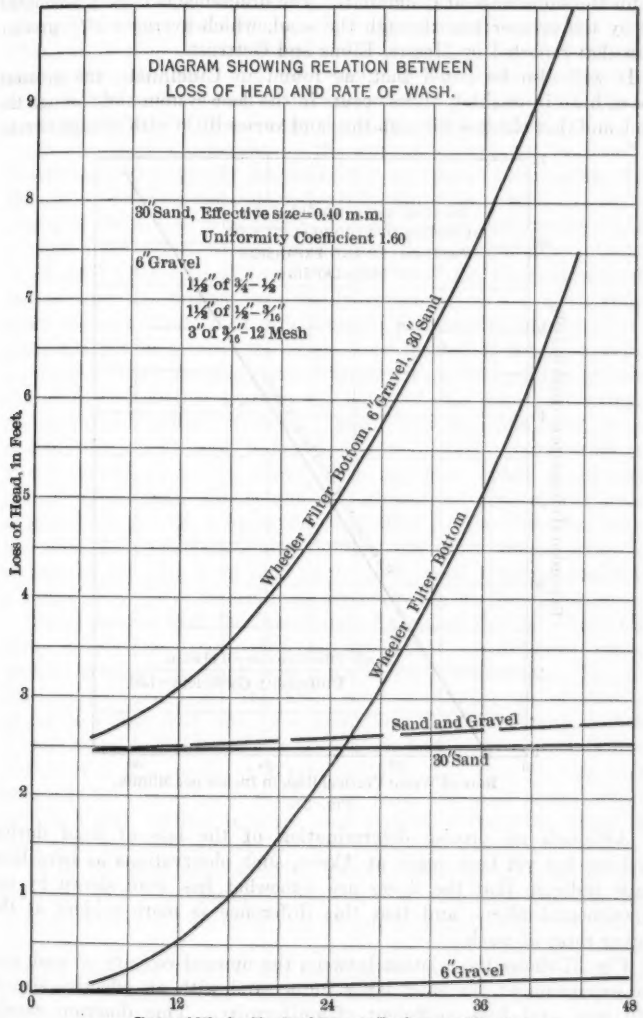

FIG. 36.

Mr. Barbour.

that the total loss for a 24-in. wash is 4.86 ft., as compared with 4.20 ft. for the same wash at Cincinnati. The difference is largely accounted for by the greater loss through the sand, which averages 25% greater than that reported by Messrs. Ellms and Gettrust.

It will also be noted that, as found in Cincinnati, the greatest loss of head in washing filters occurs in the floor system and through the sand, and that the loss through the sand varies little with change of rate.

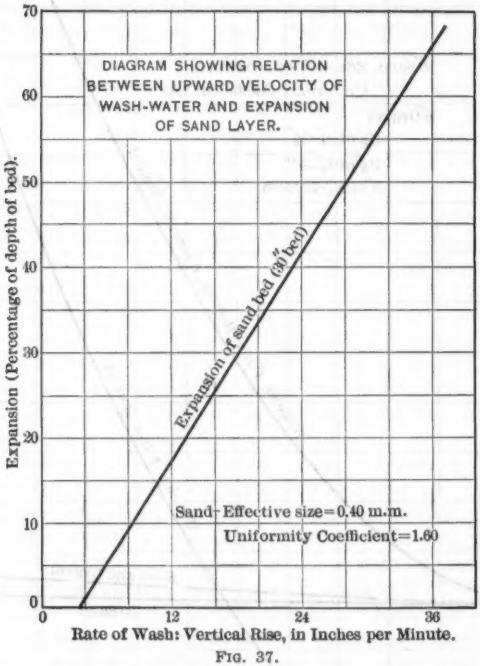

FIG. 37.

Although no precise determination of the loss of head during washing has yet been made at Akron, such observations as have been made indicate that the losses are somewhat less than shown by the experimental filters, and that this difference is more evident at the higher rates of wash.

Fig. 37 shows the relation between the upward velocity of wash and the expansion of the sand layer for a sand with an effective size of 0.40 mm. and 1.60 coefficient of uniformity. This diagram closely checks the curve of expansion for the sand with an effective size of 0.41 mm. shown on Fig. 19.

Mr. Barbour.

As pointed out by the authors, it is very necessary, in determining the height at which the gutters should be placed above the sand, to take into account the reduction in horizontal section by the gutters. Thus, at Akron, the horizontal area of the gutters is 30% of the total area of the filter, and the velocity of the wash-water equivalent to 24 in. per min., based on the area below the gutters, is equal to a velocity of 31.2 in. per min. at the plane of the gutters.

In any case, the height of the gutters should not be based too closely on experimentally determined expansions of clean sand. When the Akron filters were put in service, the sand, which as delivered averaged about 0.40 mm., with a coefficient of uniformity of 1.50, was given ten 5-min. washes at the rate of 24 in. per min. About 1½ in. of sand were scraped from the surface of the filters during these washes, and the surface was finally composed of a sand having an effective size of from 0.30 to 0.35 mm. For several months after the plant was put in service, the filters were washed at the rate of 24 in. per min., without apparent loss of sand, but as the sand grains became coated with vegetable matter, the color of the water averaging 45, the expansion gradually increased, and it has been necessary, in order to avoid the loss of sand, to lower the rate of wash progressively until, at the present time, it is about 17 in. per min. This would suggest that, in determining the height of gutters from experimental results, a leeway should be allowed for the effect of the filtering material becoming dirty, and therefore lighter. In other words, data based on experiments with clean sand provide a basis of judgment rather than a means of precisely determining the necessary height of gutter.

In connection with the furnishing of the sand for the Akron filters, some interesting experiments on the effect of different rates of wash in grading the sand were made by Mr. Williamson. The specifications required that "the filter sand shall have an effective size of not less than 0.35 mm., nor more than 0.44 mm., and shall have a uniformity coefficient of not more than 1.65." After specifying ten washes of 5 min. each, at a rate of 24 in. per min., it was further required that "samples of sand taken from the sand layers after the sand had been washed in place, and especially from the upper inch, shall meet the requirements for size heretofore specified."

With the gradation resulting from a wash at the rate of 24 in. per min., this specification is equivalent to requiring that the upper inch shall have an effective size of not less than 0.35 mm., and the lower inch an effective size not greater than 0.44 mm. To determine whether the sand which it was proposed to use at Akron would fulfill these requirements after washing, the experimental filter already described was filled to a depth of 30 in., and washed at various rates, samples being taken at different depths by thin, brass cylinders inserted through holes drilled in the sides of the filter.

Mr. Barbour.

The sand, as delivered, had an effective size of 0.34 mm. and 1.82 coefficient of uniformity. After washing for 6 min. at a rate of 16.6 in. per min., the original 30 in. was increased to 32.2 in., and a sample from the top inch had an effective size of 0.17 mm. and a 1.41 coefficient of uniformity. Then 2 in. were scraped from the surface, and the filter was again washed at a rate of 17.7 in. per min. after which seven samples were taken at the depths shown in Part A of Table 7.

32	29 1/4	0.43	1.49

After taking Sample No. 9, the filter was washed several times at rates varying from 13 to 25 in. per min., and 1/2 in. was scraped from the surface, making a total of 2 1/2 in. removed by scraping. Then 2 1/4 in. of the original sand were added, and the filter was washed four times at a rate of 26 in. per min., 1 in. of the surface sand being

removed in two scrapings of ¾ and ½ in. after the second and fourth washes, respectively. The filter was then given two 5-min. washings at 26 in. per min., and Samples Nos. 14 to 19 (Part B), Table 7, were collected. Mr. Barbour.

The filter was then given two washes at 13.1 in. per min., and Samples Nos. 21 to 26 (Part C), Table 7, were collected.

Again, the sand was given a 10-min. wash at the rate of 10.5 in. per min., and Samples Nos. 27 to 32 (Part D), Table 7, were collected.

A comparison of the results noted in Table 7 makes it evident that the higher the rate, the greater the difference between the effective size of the top and bottom layers, and the lower the coefficient of uniformity of each layer; or, in other words, the higher the rate, the more nearly is the sand graded into layers in which the particles are of the same size. Also, it is shown that, with the sand used, gradation did not result from a wash as low as 10.5 in. per min.

Gradation of the sand is immediately indicated by an increase in volume, and, when a low-rate wash is applied, the loss of gradation is shown at once by the lower elevation of the sand surface after washing.

In the experiments just described, the total depth of sand placed in the filters was 32.5 in.; after removing 3½ in. by scraping, the depth of the sand bed, following a wash at the rate of 26 in. per min., was 30¾ in., and, after a wash at the rate of 10.5 in. per min., this depth was 29¼ in.

The gradation effected by high-rate washes suggests that a reasonable specification for filter sand would define the effective size of the surface layer after washing, and would permit a higher coefficient of uniformity than has been generally required in the past, or one which would result in the bottom layer of sand grading more evenly into the top layer of gravel.

GEORGE A. JOHNSON,* M. AM. SOC. C. E. (by letter).—This paper presents some very instructive data based on experiments which obviously were made with painstaking care. Cincinnati was the first large city to adopt the high-velocity wash idea, although in numerous small plants this method has been practiced for many years. The New York sectional wash filter, which has been used for more than 20 years, embodies the same principles, and the old Hyatt shot-filled strainers were the forerunners of the type of filter bottom described by the authors. It was their purpose, also, to overcome the undesirable feature of gravel and sand mixing and to obtain even distribution of the wash-water; and these were the chief objects sought in the Cincinnati work. Hopper-shaped troughs, running lengthwise of the Mr. Johnson.

* New York City.

Mr. Johnson.

filter tank, the channels being covered with perforated brass strainer plates, is an idea first patented by Hyatt 17 years ago.

The upward velocities of flow of wash-water used by the authors, namely, 15 gal. per sq. ft. per min., are about double those commonly used where compressed air is applied preliminary to the actual washing of the filter. In some places, where relatively high-velocity washing is used—Akron, for example—a rate of 10.6 gal. per sq. ft. per min. appears to be giving satisfaction. At other places the wash-water is applied at a rate represented by about the mean of these two.

The omission of compressed air agitation, as an aid in the washing process, has never been looked on by the writer with unqualified approval. It is his belief that some form of scrubbing of the sand grains usually should precede the application of the wash-water. When treating waters containing large quantities of organic matter, the sand grains become heavily coated therewith, and, if these films are not rubbed off, the sand layer becomes very much lighter, and, even with moderately high wash-water velocities, considerable sand is lost during the washing process. Furthermore, the tendency is greater for mud balls to form, and these, being lighter than the sand, but heavy enough to resist moderately high wash-water velocities, are not removed from the filter, and, growing in size and weight, sink into the interior to clog the filter in spots and thus serve as a direct cause of unequal rates of filtration and wash-water application.

Air agitation, or mechanical stirring, serves to rub the sand grains together far more vigorously than the application of wash-water alone at high velocities. If it were not for the mud-ball feature, common in waters which contain large quantities of vegetable organic matter, the agitation afforded by the high-velocity wash probably would almost always prove adequate; but, in the treatment of some waters of this class, the writer believes that to dispense with the "scrubbing" phase of filter washing is simply paving the way for the complications previously noted.

Mr. Barbour has mentioned this feature, as observed at the Akron plant, and that the sand beds, through the agency of the vegetable matter in the raw water, become more bulky. Consequently, they must become lighter, and the vertical rise of the sand layer during washing must be correspondingly greater. This must mean a waste of sand, unless the critical velocity of the applied wash-water is watched sharply and never allowed to become great enough to permit sand to be carried from the filter. Such restrictions as this may reduce the washing efficiency materially, by allowing balls of this vegetable matter to form and remain in the bed. The writer believes decidedly that, in the treatment of some waters, air agitation, preliminary to the washing process proper, is necessary.

JAMES W. ARMSTRONG,* M. AM. SOC. C. E. (by letter).—At the time Cincinnati was considering the question of the omission of wire screens between the filter gravel and filter sand, and before the experiments mentioned in this paper were undertaken, plans were in preparation for the Montebello filters at Baltimore, Md. Mr. Armstrong.

In order to determine whether or not it would be possible to operate the filters successfully without placing wire screens between the gravel and sand layers, a small wooden filter tank, Fig. 38, was built, early in 1913, somewhat similar to that at Cincinnati. It was 3 ft. by 3½ ft. in plan, and 9 ft. deep. The wash-water trough was 5 ft. 6 in. above the bottom of the tank. Wash-water was admitted to the filters through a wrought-iron pipe manifold with 1½-in. laterals 6 in. from center to center. The laterals had $\frac{7}{32}$-in. holes drilled in them 2½ in. from center to center.

The results of the Baltimore experiments practically coincide with those obtained by Messrs. Ellms and Gettrust, and, in connection with their carefully prepared paper, are of interest only from the fact that, in a number of cases, the wash-water was applied at a much higher rate.

The first few runs were made with both gravel and sand in place. The gravel was 14½ in. deep, and well graded between 3 in. and $\frac{3}{16}$ in. in diameter. There was a depth of 24 in. of sand on top of the gravel. It was found that when the wash-water was passed upward through the gravel and sand at rates giving a vertical rise as high as 2 ft. per min., there was no loss of sand, but when the rate gave a vertical rise of from 2.5 to 2.8 ft. per min., considerable sand was lost.

As the experiments were conducted for the sole purpose of determining the action of the gravel layers under high rates of wash, further experiments with the sand were discontinued, the gravel was re-arranged in several ways, and runs were made with the holes in the manifold system turned toward the bottom of the tank, and others were made with the holes turned upward so that the jets of water impinged directly on the gravel in a direction tending to lift it.

The water for washing was supplied through a 3-in. pipe, directly from the high-service pumps, at a pressure of from 115 to 125 lb. per sq. in. The water was measured with a 3-in. Gem meter, and was applied at rates giving a vertical rise varying from 2 to 6 ft. per min. In no case was there a movement of the top gravel layer sufficient to create any permanent disturbance. After the water had ceased flowing, the gravel returned immediately to its former position, and no evidence existed that there had been any disturbance.

A glass plate in the side of the tank permitted observation of the top surfaces of the gravel and the influence of the water jets on it during the period of washing. Details regarding the depth and size

* Baltimore, Md.

Mr. Armstrong.

of the different gravel layers, the rate of wash and the effect of the water on the gravel surfaces are indicated in Table 8.

EXPERIMENTAL FILTER TANK AT BALTIMORE, 1913.

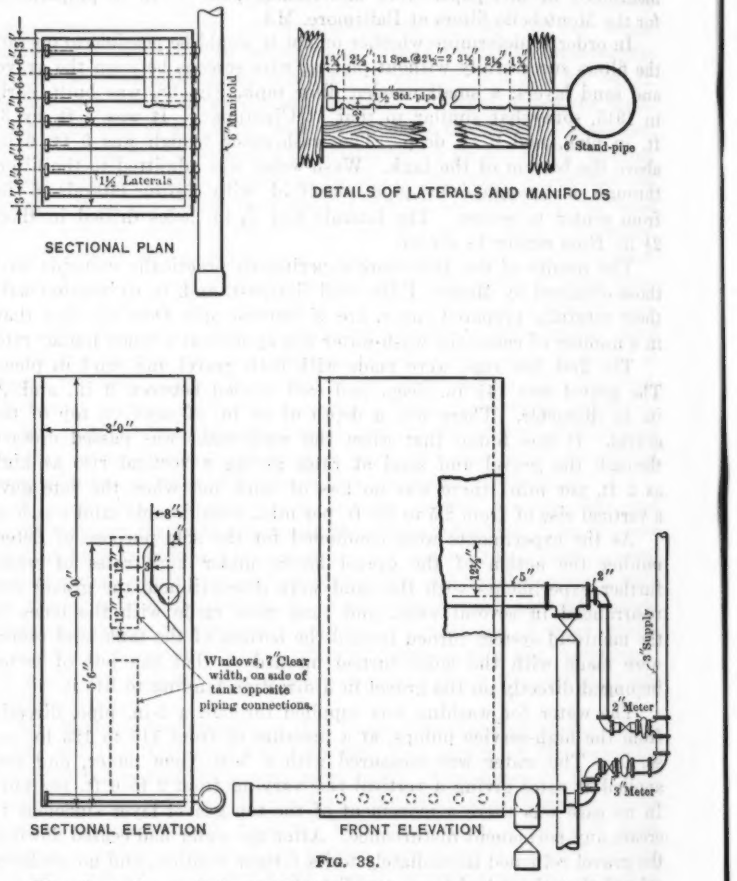

FIG. 38.

The facts learned from these experiments were sufficient to convince those in charge of the design that the wire screens could be safely omitted, and the Montebello filters were accordingly built without them. There was a depth of 14 in. of gravel and 24 in. of sand in each of the filters.

Messrs. Ellms and Gettrust.

JOSEPH W. ELLMS,* M. AM. SOC. C. E., and JOHN S. GETTRUST,† ESQ. (by letter).—The writers are gratified that this paper has been so well discussed, and that it has brought forth so much valuable and hitherto unpublished information. Certain features of filter design not directly related to the subject matter of the paper have been brought into the discussion, and have served to heighten its interest. The close relationship between type of strainer system, method of agitation, and character of filter bed is evident from a careful reading of the experimental data submitted.

Mr. Fuller's experience with breaking strainer plates and hook-bolts, coupled with the writers' experience in the breaking of hook-bolts, would appear to indicate that, in the design of this type of strainer system, too little attention has been paid to the stresses created by the upward flow of the wash-water, and especially to those stresses developed at the instant of opening the wash-water valve.

Mr. Manahan seems to be of the opinion that the wearing away of the brass wire-cloth, by the movement of the sand particles through it, had as much to do with its deterioration as did corrosion. It is probably true that the location of the screen subjected it to considerable erosion, and to some strain produced by the pressure of the wash-water on those portions of the cloth where the meshes had become clogged gradually by the lodgment of fine particles of gravel in them; but it is the writers' belief that actual solution of the zinc and copper of the brass by the water passing through the screen had more to do with its destruction than the mechanical agencies. A close examination of the wire-cloth indicates a change in the character of the alloy. It is true that some corrosion of the strainer plates themselves has taken place, but, as they are of much heavier metal, and as they are not subjected to mechanical abrasion in any way, their life has not been affected materially.

The greater latitude permissible in specifications for filter sand which is to be subjected to high-velocity washing seems to be the opinion of both Mr. Stephenson and Mr. Barbour. Mr. Barbour's method of specifying sand for the Akron filter plant seems to the writers a most sensible one, and worthy of general adoption.

The valuable data submitted by Messrs. Willcomb, Barbour, Pirnie, and Armstrong are in accord with the information secured by the writers, and in general their conclusions are the same. Mr. Pirnie's conclusion: "If a filter can be constructed so that the wash-water has a uniform velocity when it passes from the gravel into the sand, there will be no tendency of the gravel and sand to mix", is sound, and sums up concisely the desirable condition to be attained. His further deduction, that all ridges are useless, the writers are inclined to

* Cincinnati, Ohio.
† Kent, Ohio.

believe is correct. All the dispersion effects, which would contribute toward destroying jet action from the strainers, may be obtained by directing the discharge from the strainers toward the bottom or floor of the tank, and by a sufficient depth of properly graded gravel over the strainer system. In the Wheeler bottom, as described by Mr. Barbour, we have as complete a destruction of the jet action of the wash-water, when the jet is directed upward, as has as yet been designed. How the rather broad ridges—necessitated by the construction of the inverted pyramids which hold the balls—will affect the effectiveness of washing in the section immediately above them is worth observing in filter plants using a bottom of this type. Messrs. Elims and Gettrust.

Mr. Armstrong's experiments are of particular interest in showing the stability of the gravel layer under very high rates of washing. These rates are much higher than would ever be required in practice.

Messrs. Willcomb, Pirnie, and Johnson advance some reasons for favoring the use of an air-wash, and seem to think that it will meet certain conditions better than a high-velocity wash. Mr. Pirnie seems to think that the escaping air will break up lumps that form on the surface of the sand, which a high-velocity wash will not do. Mr. Johnson contends that some form of scrubbing action should precede the application of the wash-water, and that the escape of the air will do much toward preventing the formation of mud balls.

The writers' observations on agitation with compressed air are not in accord with these conclusions, and though admitting that the escape of air from a filter bed covered with a layer of water seems to produce an agitation of the sand particles, there is in reality no movement of them, or at the most only a very slight movement of the very finest particles at the surface. Any deposited colloidal coating on the sand, of course, will be broken, and will be projected in part into the overlying water; but the same effect is also produced by the rising currents of wash-water as they leave the channels between the sand grains, break through the colloidal coating on the surface, and enter the main body of the water above the sand. Scrubbing or the rubbing of the particles against each other does not take place when air is forced into the bed in the usual way prior to the application of the wash-water.

The rubbing of the sand particles against each other does take place, however, when the bed is floated by the high-velocity method of washing. In fact, the chief reason for adopting that method in the design of the Cincinnati filtration plant was, that the earlier experiments, made by one of the writers, showed that this method produced this scrubbing effect, and in a measure reproduced the action of mechanical rakes.

The formation of mud balls in filter beds, and the adhesion of the dirty sand to the sides of the tanks were common enough phe-

Messrs. Ellms and Gettrust.

nomena before the high-velocity method of washing was developed, and, consequently, their occurrence in filters cannot be charged to this particular method of washing. Mud balls in the sand, or mud banks on the sides of the tanks, or hard areas in the sand bed, are due to an insufficient quantity of wash-water, or to none at all in the spots affected. This condition may arise from the improper distribution of the wash-water, which must be due primarily to the type of strainer system used, and to the manner in which the rising wash-water is distributed after leaving the strainer openings. If forcing compressed air into the sand bed has any agitating effect at all on the coated sand grains that lay at or near the surface—as some appear to believe, but which the writers have failed to detect—it is undoubtedly true that the application of wash-water at a rate sufficient to float the sand bed effects a very much greater scrubbing action of the sand grains, and all are agreed that this is the desirable effect to be produced by any method of agitation that may be used.

Paper No. 1370

THE EFFECTS OF STRAINING STRUCTURAL STEEL AND WROUGHT IRON*

By Henry S. Prichard, M. Am. Soc. C. E.

With Discussion by Messrs. J. A. L. Waddell, Henry B. Seaman, C. A. P. Turner, T. D. Lynch, James E. Howard, H. F. Moore, F. N. Speller, J. A. McCulloch, Ernst F. Jonson, T. E. Stanton, Henry M. Howe, A. C. Irwin, David A. Molitor, Clement E. Chase, and Henry S. Prichard.

Synopsis.

Iron, in combination and mixture with small proportions of carbon and other substances, and variously treated in its manufacture, is produced for commercial purposes in many varieties, which differ greatly in strength and ductility but little as regards the rate at which, within the elastic limit, dimensions and bulk are changed by straining at ordinary atmospheric temperatures. One variety, made by welding plastic masses which contain very little carbon and some slag, is termed wrought iron. This is a ductile variety, comparatively low in strength. Most of the other varieties are known as steel. One now little used variety of steel, slag-bearing or weld steel, is made from wrought iron by heating and adding carbon, but without remelting. The other varieties of steel are slagless and, when not simply cast, are made from steel castings (termed ingots) by mechanical and thermal treatment. The different varieties of steel cover a large range of strength, ductility, and hardness, the comparatively soft varieties being more ductile than wrought iron, and the very softest being slightly weaker.

* Presented at the meeting of March 1st, 1916.

The changes in dimensions and shape which take place in pieces of steel or wrought iron when they are strained are brought about either in the first of two certain ways, or in both of these ways in conjunction, depending on the severity of the straining. When strained in the first way, the changes in dimensions, shape, and bulk of a strained piece are effected entirely by changes in dimensions, shapes, and bulks of the particles of the piece, without any sensible slipping of one particle over another. A piece thus strained, on the cessation of the forces which caused the straining, returns to its original size and shape in every part and in every particular; hence the piece is not over-strained and, within the limits of straining within which its each and every part acts in this way, is perfectly elastic. The second way in which changes are effected is by the sliding of particles one over the other under shearing forces, whether the forces are simple shears or the shearing components of tension or compression. Such sliding is caused by straining the metal beyond its capacity to resist shear, and such straining is called over-straining. The changes in dimension and shape resulting therefrom are permanent; but the sliding particles, excepting metal between the sliding surfaces, remain elastic within themselves, and return to their former dimensions and shapes, though in new positions and with changed inclinations, on the cessation of the forces which strained them; hence an over-strained piece is still partly elastic, and tends, to that extent, to recover its original dimensions and shape on the cessation of straining forces.

The elastic limit of steel and wrought iron, though expressed in cases of direct stress with respect to said stress, is determined by the limit to shearing resistance, and is the same in tension and compression, for the reason that the shearing components are the same.

In ordinary testing of structual steel and wrought iron, in tension or compression, the first indication that the elastic limit has been exceeded is usually a breaking of the mill scale, when there is any, followed by a sudden and pronounced yielding. The point at which the pronounced yielding occurs is known as the yield point. When micrometers are used to measure the elongations or compressions, a readily appreciable but lesser yielding can usually, but not always, be observed prior to and within a few thousand pounds per square inch of the yield point. Graphically represented, this preliminary

yielding is, roughly, in the form of a curve tangent to the line representing elastic elongation or compression. The beginning of this preliminary yielding is termed the "proportional elastic limit", or simply the "elastic limit", which is the older, more familiar, and better designation.

When measurements are made with great precision on long gauged lengths, slight imperfections in elasticity, due to initial internal stresses developed during and by the processes of manufacture, can usually be detected at stress intensities far below the point known as the elastic limit in pieces of steel or wrought iron strained for the first time; but, in pieces subjected to only one kind of stress, these imperfections are not important, as the permanent sets in such pieces are very small and the elasticity can be perfected to the elastic limit by straining to that limit. In pieces subjected to alternate direct tension and compression, the elasticity can similarly be perfected; but, if the alternations are rapid and continuous, it cannot be perfected to as high a limit.

When a piece of steel or wrought iron is over-strained, the metal between the surfaces of the sliding particles is viscous, during the over-straining action, in the popular sense of being sticky; that is, it adheres to the adjoining solid particles and has great tensional resistance, and—in the scientific sense of flowing under force but offering resistance as regards the velocity of flow—the flow increases with the intensity of the force and decreases with the degree of viscosity, being very slow when the viscosity is very great. The viscous metal, like the substance pitch, is a liquid, judged by its properties, but, like pitch, is solid in its appearance. The energy which makes and keeps the metal liquid is not in this case applied as heat, but as mechanical force.

Any film of steel or wrought iron made viscous by over-straining at an ordinary atmospheric temperature is at a temperature far below its normal freezing point, and, when released from the shear which makes it viscous, resolidifies with great rapidity. There is considerable evidence to show that after the film has resolidified it is amorphous, like glass, and not crystalline in its structure, and experiments lead to the conclusion that in its supposed amorphous condition it is much stronger than in the original crystalline state in which the solidification had been gradual.

Over-strained steel or wrought-iron pieces suffer temporary loss of strength while the viscous metal is resolidifying; but, as the viscous metal resolidifies with great rapidity on the release of stress, an over-strained piece regains most of its elasticity within a few minutes after the removal of the external forces. If, however, the straining has been much above the yield point, the elastic solid portion of the metal in its recoil will act on the viscous portion and prevent complete solidification for hours or even days and weeks.

When steel or wrought iron is ruinously over-strained, the solid particles will tear apart instead of simply sliding one over the other, and will have to be reheated, or, in severe cases, entirely remelted, before they can again be united. Small tears, not in themselves discernible, will be extended by long-continued or oft-repeated stresses until they cause rupture. This phenomenon is known as fatigue. The tears start where the metal is weakest, presumably at flaws, of which there are probably many of microscopic size in every piece of steel and iron. Experiments and experience indicate that during the life of structures, as determined by other considerations, failure from fatigue does not occur in steel and wrought iron of good quality under repeated stresses less than the elastic limit; but experiments also indicate that such failure is likely to occur under a long-continued succession of rapidly alternating stresses of intensity less than the elastic limit.

For the conditions of ordinary railway bridge practice, the provision for alternate stresses specified by the American Railway Engineering Association seems to be reasonable.

With proper treatment, steel or wrought iron can have its elastic limit raised by over-straining, as in cold-drawn and cold-rolled steel or iron, considerably above the yield point of the ordinary hot-rolled or forged metal; this fact is of great advantage to the manufacturer, and is useful in adjusting and increasing the capacity of some structural parts subjected to bending stresses, but of little value to tension and compression members in service, as the great elongation or compression when a member is strained above the yield point will cause failure of the member, or the entire structure, from distortion, and thus preclude the possibility of subsequent benefit from an enhanced elastic limit.

Fatigue formulas, so-called, have been devised, which are intended to give the greatest strength which can be developed in a piece of steel or wrought iron by straining without resulting in ultimate failure from fatigue. As the greatest strength of steel or wrought iron under repeated stresses is beyond, and in some cases far beyond, the yield point, such a formula, even if perfect, would not be applicable to the design of structural tension and compression members.

General Description of Steel and Wrought Iron.

Steel and wrought iron are essentially iron containing carbon in quantity not exceeding about 0.3% in wrought iron, usually less than 0.9% in steel, much less in structural steel, and not exceeding 2.2% in any steel. Other constituent and foreign substances are always present, some designedly and some unavoidably, some beneficial and some harmful.

Wrought iron differs from slagless steel in the limit to the percentage of carbon, in containing slag, and in being produced by the welding together of small slag-bearing masses, instead of being cast from a melt before rolling or forging. It differs from slag-bearing or weld steel, a now little used kind, in containing less carbon. Steel and wrought iron have a crystalline structure in which the crystalline formation has been more or less interfered with by treatment.

In general, treatment of steel and wrought iron is chemical, metallurgical, thermal, and mechanical. Mechanical treatment is possible because these metals are plastic; that is, they are capable of being more or less moulded by force, even when cold.

Whenever structural steel and wrought iron are strained beyond their elastic limits they are thereby treated to their benefit or injury.

The effect of stress in a piece of steel or wrought iron is to alter its size and shape temporarily, if the stress is within the elastic limit, or permanently, if beyond it, and, if beyond it, to alter the properties of the metal.

Elasticity.

Elasticity, as applied to solids, is the property of returning to original size and shape on removal of stress.

Proportionality of alteration in size and shape to stress is not essential to the conception of perfect elasticity, but experiments indi-

cate that when the elasticity is perfect and the stress is simple tension or compression, such proportionality actually exists. When the stress is compound, the alteration in length in the direction of any one of the stresses is not the same as it would be under a simple stress in that direction, but if all the stresses are increased or decreased in any given proportion, within the elastic limit, the alterations in size and shape will be in the same proportion.

As regards elasticity, steel and wrought iron are isotropic; that is, when their elasticity is perfect, it is the same in all directions around any point.

The ratio of simple stress to alteration in length is expressed by a factor called the modulus of elasticity; this may be defined as one million times the simple stress per square inch required to increase or decrease the length of a bar the one-millionth part of its length.

Many carefully conducted experiments indicate that, at ordinary atmospheric temperatures, the modulus of elasticity of slagless steel, in either tension or compression, does not vary much from 30 000 000 lb. for all grades (this is the technical way of stating that it takes about 30 lb. per sq. in. to stretch or compress such steel the one-millionth part of its length), as shown in Table 1. Wrought iron, doubtless on account of the included slag with which the iron is intimately associated, has a somewhat lower modulus, and the same is probably true of slag-bearing or weld-steel, which is made, what little there is of it, from wrought iron without melting.

There are numerous tests in which the recorded alterations in length seem to indicate erratic variations of considerable magnitude in the modulus of elasticity, but they are probably either in error, or, on account of disturbing elements, are not applicable to the determination of the modulus. Additional and conclusive experiments in this regard are a desideratum.

Simple longitudinal tension, in addition to causing longitudinal elongation, causes lateral contraction; and simple longitudinal compression, in addition to causing longitudinal shortening, causes lateral expansion. The ratio of contraction or expansion, perpendicular to the direction of the stress, to elongation or shortening in the direction of the stress, is termed Poisson's ratio. If the bulk of a body is assumed to increase with pull and decrease with pressure, applied in either one or all directions, Poisson's ratio must be less than $\frac{1}{4}$. For

instance, if equal pressures were applied on the six faces of a cube, and Poisson's ratio were more than $\frac{1}{2}$, then the expansion in the direction of each pair of forces from the combined influence of the other two pairs would be more than $\frac{1}{2}$ plus $\frac{1}{2}$ of the shortening, or greater than the shortening, thereby increasing all the dimensions and the bulk of the cube; or, if Poisson's ratio were just $\frac{1}{2}$, there would be no increase or decrease; but, if less than $\frac{1}{2}$, there would be a decrease in bulk.

TABLE 1.—Comparative Tests in Tension and Compression of $1\frac{1}{4}$-In. Diameter Open-Hearth Steel Bars of Various Grades, Turned to Specimens from that Size.

Compression Specimens 1.0092 in. Diameter, 12 in. Long.
Tension Specimens, 1.0092 in. and sundry Diameters; Gauged Length, 30 in.

Tests made at the Watertown Arsenal, and given in the Reports for the Year 1886, pp. 1635-1653; and for 1887, pp. 802-822.

* The yield points are not specifically noted in the records, but in most cases are indicated: in tension, by increase in elongation under reduced loads and by great differences in elongations recorded for slightly differing loads; and, in compression, by buckling to failure after a slight increase in rate of shortening.

Poisson arrived at the existence of this contraction or expansion, at right angles to pull or pressure, from theoretical considerations; and his theory led him to assign to his ratio a value of $\frac{1}{4}$, but his theory has been questioned. Experiments indicate that the value for steel is between $\frac{1}{4}$ and $\frac{1}{3}$.

The behavior of an isotropic elastic solid body, strained within the limits of its elasticity, is entirely determined by its modulus of elasticity and Poisson's ratio. Writers on theoretical mechanics have found it convenient to introduce other constants, but they are not needed for the purposes of this paper.

Elasticity is one of the most useful properties of matter. Without it, structures and machines would be impossible. It is the foundation on which many useful engineering theories are based, and it affords the mathematically inclined endless possibilities for intricate analysis, but to the practical engineer the most important question regarding it is its limit. The limits to the elasticity of steel and of wrought iron are closely related to the resistance of these metals to shear.

Shear.

The internal forces acting on any plane within a body can be resolved into a tension or compression at right angles to the plane—that is, normal to it—and a shear tangential to it.

When the force is a simple pull or pressure on a bar, as in Fig. 1 (drawn for pressure), the tension or compression has a maximum intensity, and the shear is zero, on a plane normal to the direction of the force; and the shear has a maximum intensity on a plane making an angle of 45° with the normal plane.

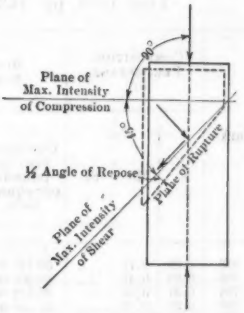

Fig. 1.

Experiments show that materials which are brittle or comminuible, "when subjected to a compressive load, fail by shearing on certain definite angles. The resistance to movement along these angles is made up of two parts; first the strength of the material to resist shearing; and second, the frictional resistance to motion along this plane." Analysis leads to the conclusion that rupture should take place on a plane making an angle with a normal plane of 45° plus one-half the angle of repose of the material. The analysis on which this conclusion is based* is supported by the results of numerous experiments and photographs of the specimens after rupture.

* J. B. Johnson's "Materials of Construction", pp. 24–28.

Under pressure, plastic materials, like structural steel and wrought iron, do not fail by shearing on any one plane, like the specimen in Fig. 1; but, after the elastic limit is passed, they simply spread, as in Fig. 2. Under pull, after the elastic limit is passed, they draw out like taffy, as in Fig. 3, to a greater or less extent, before rupture.

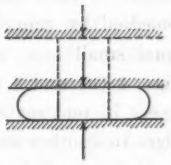

FIG. 2.

The fact that the deformation of materials depicted in Figs. 2 and 3 was caused by failure to resist shear is not evident from simple observation.

The usual conception of movement under shearing stress is that of sliding, but there is no visible evidence of the sliding of one particle on another before the elastic limit is reached. Change in shape within the elastic limit is not due to any sliding over one another of the individual grains or crystals; instead of this, each grain, no matter how minute, is itself deformed. What takes place among the molecules of the material under shear is a matter of speculation.

FIG. 3.

When the elastic limit is exceeded, the ensuing deformation is caused largely by actual sliding of the particles.

"These slips are seen under the microscope as sharply defined lines which appear on the polished surface of each grain as soon as the yield-point in any process of straining has been reached."*

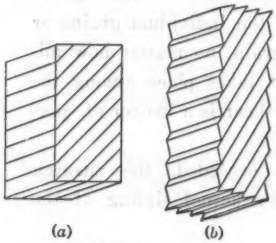
Of course, it is impossible to know or illustrate just how the particles move and slide in deformation beyond the elastic limit, but equivalent movements and slips can be conceived to illustrate how the geometry of such deformation can be accounted for on the hypothesis of sliding and rotating particles, as follows:

A square bar, made up of layers inclined at an angle of 45°, as in Fig. 4 (*a*), could be elongated longitudinally and contracted laterally by rotating the layers and sliding them over one another, as in Fig. 4 (*b*). Two of the sides of such a bar would not be plane, but, if the layers were very thin, the surfaces would appear to be plane with fine markings.

* James Alfred Ewing, in Encyclopædia Britannica, 11th Ed., Vol. XXV, p. 1018.

Such a bar would be contracted in only one lateral direction, whereas bars under simple pull are contracted in two lateral directions perpendicular to each other. This defect in the supposititious bar can be remedied by conceiving the bar as divided into a large number of equal small bars, each, in turn, divided into inclined layers, as in Figs. 4 (*a*) and 4 (*b*), but grouped so that the inclined edges of the layers in one set of small bars would be adjacent to the horizontal edges in another set, as in Fig. 5.

If the small bars into which the large bar is conceived as divided are very small, and the surface of the large bar is conceived to be polished, the edges of the layers would appear as straight lines. The angles which these lines would make with a plane normal to the direction of the pull would have a tangent equal to $\frac{1}{2}$ tan. 45°, or 0.5,



(*a*) (*b*)

FIG. 4.

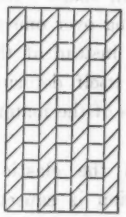


FIG. 5.

which corresponds to an angle of 26° 34′. Such lines are known as Luder's lines. Their occurrence in pulling tests, as indicated in specimens of full thickness by the breaking of the mill scale, is a very common phenomenon. It is evident from simple inspection that the angle these lines make with a plane normal to the direction of the pull is usually much less than 45° and often not far from the angle of 26° 34′ as just deduced. Before this deduction was made, Professor Ewing* stated that this angle had been found to be about 25 degrees. Two sets of Luder's lines, sloping in opposite directions, appear in tests, which shows that the actual condition is more intricate than the equivalent condition assumed. The condition assumed, however, makes it evident that the lines do not directly indicate the slopes of the planes on which slipping occurs, but instead, the mean inclinations of the edges of the planes.

* Encyclopædia Britannica, 11th Ed., Vol. XXV, p. 1016.

Lateral expansion under longitudinal pressure can be accounted for in a manner similar to that for lateral contraction under longitudinal pull.

The foregoing explanation of deformation under pull raises the question: What holds the grains together in tension after they sever their original connections and rotate and slide? The answer involves a consideration of the nature of the change which occurs in the condition of steel and wrought iron when the limits to elasticity are exceeded.

The Elastic Limit.

Material which can be constrained by mechanical force into new forms without breach of continuity is said to be plastic; hence, wrought iron, soft steel, and, to some extent, even hard steel, are plastic. They are seldom characterized as plastic, but wrought iron and soft steel are described as malleable and ductile, which terms imply a great range of plasticity. Some of their characteristics while flowing are those of a liquid.

Liquids have no static resistance to shear, but have cohesion* among their molecules, which is nil at their boiling point and increases toward their freezing point.† Cohesion without static resistance to shear does not prevent but does impede flowing, and this property is termed viscosity. Liquids, however, are not usually termed viscous unless they possess a high degree of viscosity. Viscous liquids not only have cohesion, but, to a greater or less extent, have the property of adhering to solids. This useful property, this glue-like stickiness, though not essential to the scientific conception of viscosity or included in the scientific definition of the term, is firmly ingrained—in fact predominates—in the popular idea of the meaning of the word. Above certain temperatures, and at ordinary temperatures under certain mechanically produced conditions, viscous portions of structural steel and wrought iron adhere strongly to the solid portions of the metal.

According to some physicists, the plastic solid is distinguished from the viscous liquid in that the former requires a certain magni-

* Newton devoted the 31st query in the last edition of his "Opticks" to molecular forces, and instanced several examples of cohesion of liquids, such as suspension of mercury in a barometer tube at more than double the height at which it usually stands.

† The surface tension diminishes as temperature rises, and when the temperature reaches that of the critical point at which the distinction between a liquid and its vapor ceases, it has been observed by Andrews that the capillary action also vanishes. James Clerk Maxwell, and Lord Rayleigh, in Encyclopædia Britannica, 11th Ed., Vol. V, p. 261.

tude of stress to be exceeded to make it flow, whereas the viscous liquid will yield to the slightest stress, but requires a certain length of time for the effect to be appreciable. This distinction is generally accepted, but is superficial.

The change from a solid to a liquid state is a radical one. Considerable energy, usually in the form of heat, is required to melt the solid, which energy is not expended in raising temperature, but in effecting molecular changes by reason of which the potential resistance to flowing is overcome and the molecules are less restricted and have greater freedom of action. It is this difference in molecular arrangement, no matter how produced, which is the real distinction between a liquid and a solid.

A certain portion of a plastic metal, when caused to flow by "a certain magnitude of stress", is a highly viscous liquid during the continuance of the flow, and even for a time after the removal of the stress; and it will be so termed in dealing with this subject.

Mr. H. E. Tresca, by applying great pressure, caused copper, silver, iron, and other metals to flow, like viscous liquids, through a small circular aperture at the bottom of a cylinder, and without breach of continuity. Parallel experiments, with layers of dough or sand plus some connecting material, proved that the particles moved along the same tracks as would be followed by a flowing cylinder of liquid.*

When structural steel and wrought iron become partly viscous and begin to flow, the elastic limit, of course, has been reached; and the converse is true: when the elastic limit is reached, structural steel and wrought iron become partly viscous and begin to flow. It is because the viscous portion of the metal acts somewhat like glue does with wood, or china cement with china, that the sliding grains or crystals adhere in their new positions, and finally, after the viscous portion has solidified, form a coherent mass.

When structural steel and wrought iron are strained for the first time after leaving the rolls or forge they are apt to have slight imperfections in elasticity, indicated by slight permanent sets, under loads far below those at which the general yield begins.

Structural parts are strained so frequently that even very slight permanent sets, if repeated and accumulative, would become ruinous

* Encyclopædia Britannica, 11th Ed., Vol. XVIII, p. 199.

in a comparatively short time. For reasons discussed in the next section—The Beneficial Effects of Strain—such increases in permanent sets, under loads below that at which the general yield begins, do not occur, and slight imperfections under such loads are of little practical importance.

Structural steel and wrought iron are not minutely homogeneous with respect to resistance to shear; that is, although small specimens of metal of good quality are nearly alike, microscopic specimens differ; but, for a considerable proportion of the metal within a specimen, the resistance is so nearly uniform that, after a certain point in stress is reached, a general yield develops under a slight increase in stress intensity.

In simple tension or compression, the yield usually culminates in a flow under a constant or decreasing force at a point called the yield point. At this point, in slowly conducted tests, the intensity of the stress frequently decreases several thousand pounds, in extreme cases as much as 10 000 lb. per sq. in.; after which it takes an increasing force to cause the metal to flow with any degree of rapidity. In some tests, the yield point is indicated by a relatively great increase in elongation or shortening under a slight increase in stress.

In ordinary specimen tests, the yield point is usually discernible by the drop of the beam, unless the steel is hard and the speed rapid. The yield point is often called the elastic limit, for the reason that in ordinary testing it is the first indication that the elastic limit has been reached. By some authorities it is called the apparent elastic limit; but yield point is the best name.

The beginning of the general yield sometimes coincides with the yield point; that is, in such cases, the general yield develops instantaneously to a flow without increase in load. More often the beginning of the general yield occurs under a stress from a few hundred to a few thousand pounds per square inch below the yield point, and is indicated by increase in rate of elongation or shortening, which increase is discernible in ordinary specimens by measuring carefully the elongation or shortening with sensitive micrometers.

By some authorities, the beginning of the general yield is called the proportional elastic limit, or the limit to proportionality, for the reason that, below this point, the elongation or shortening indicated in simple tension and compression tests is nearly proportional to

stress, even on the first application of the load. In the detailed reports of the many scientifically conducted tests at the Watertown Arsenal, this point is called the elastic limit; which is the better name for it, for three reasons: first, the elasticity of the metal up to this point can be perfected by straining, as explained in the next section—The Beneficial Effects of Strain; second, the permanent sets below this point do not increase under repeated or continued stresses, and are too slight to be of any practical importance; third, proportionality of elongation or compression to stress is not the essential but simply an observed characteristic of elasticity.

When the gauged lengths are long and the measurements are made with great precision, the true elastic limit, as some authorities term it, is usually very low the first time the metal is strained; in many cases it has been observed to be as low as 5 000 lb. per sq. in. This point, for reasons explained in the next section, is of no practical importance. It is doubtful, in fact, whether, when structural steel and wrought iron are strained for the first time, there is any point below which elasticity and proportionality are absolutely perfect.

The elastic limit, defined as the beginning of the general yield, is the most important measure of the most important property of structural steel and wrought iron, because it is the criterion of permanent strength without, or with only slight, permanent deformation, and because it is the limit to the applicability of those methods of determining stresses and deformations which are based on the proportionality of stresses to deformation.

Experiments have shown that the yield point and elastic limit of structural steel and wrought iron are practically the same in compression as in tension. As this fact is crucial in explaining what takes place at the elastic limit, the results of pertinent experiments are given in Tables 1 and 2. The tests in Table 1 are part of a series of scientific experiments made by the Government's engineers at the Watertown Arsenal, and are notable for their precision and the wide range of grades covered—from carbon 0.09 to 0.97 per cent. The tests by the late Charles A. Marshall, M. Am. Soc. C. E., in Table 2, are part of what was probably the most exhaustive comparison of steel and wrought iron in compression with steel and wrought iron in tension. For both of these metals all his results are substantially in accord with those in Table 2.

TABLE 2.—Compression and Tension Tests of Steel Bars, all from the Same Blow of Bessemer Steel "as from Rolls".

Tests made by the late Charles A. Marshall, M. Am. Soc. C. E. *Transactions*, Am. Soc. C. E., Vol. XVII, p. 68.

Pieces for Tension Tests cut from same bars used in Compression Tests. All tests were of full-sized bars, except specimens tension tests of 3-in. bars more than 1 in. thick. Bars tested in compression had flat ends.

Notes.—Results for specimens 2 diameters long are the average of two tests each, except for ¾ in. round and 1 in. square. All other results in compression are those of single tests. "The short compression specimens were removed and measured with a measuring machine." "The tendency is with very short specimens, either in tension or compression, to get too high values for elastic limit."

* "Bar finished at very low heat."

† Elastic limit "by beam" is now frequently termed yield point, which is better practice, as the point properly termed elastic limit and sometimes termed proportional elastic limit is usually somewhat lower.

This equality of the yield point in tension and compression shows that resistance to flowing is just as great when there is a pull normal to the direction of the shear as when there is a pressure. It seems fair, therefore, to infer that flowing occurs just as soon as, and not before, the resistance to shearing is overcome, uninfluenced by the kind (tension or compression) or intensity of the normal component, and irrespective of whether the shear was produced by simple or compound stresses. What seems to be a yielding to simple tension or compression is really a flowing under shear.

The question whether maximum stress, maximum strain (linear), or maximum shear is the critical consideration has been much debated during the last fifteen years. That shear is the critical consideration is supported by the experiments and analysis of J. J. Guest,* Professor E. L. Hancock,† and others. For plastic materials, the conclusion seems inevitable that shear is the critical consideration as regards the elastic limit. Frictional resistance, which in cases of comminuible materials supplements resistance to shear (see page 1436), cannot be much of an element in the flowing of plastic metals, for the reason that the flowing metal is either all viscous liquid or solid particles mixed with and well lubricated by viscous liquid. There is no angle of repose of a liquid; otherwise it could be permanently piled, like sand or coal.

In cases of simple tension and compression, it is the custom to state the elastic limit in terms of the intensity of the tension or compression. This custom is simple, and it is not advisable to attempt to change it, even though it is not tension or compression but shear that is critical. It is well, however, to be able to state for plastic metals the elastic limit in terms of shear intensity, so that it can be generally applied to compound as well as simple stresses. From the fact that the maximum shear occurs in a plane making an angle of 45° with the direction of a simple tension or compression, it can be readily shown that the quantity which expresses the elastic limit in terms of shear intensity is one-half the quantity which, in cases of simple tension or compression, expresses the intensity of the tension or compression at the moment the elastic limit is reached. For instance, if the elastic limit for a certain quality of steel has been definitely found by

* *Phil. Mag.*, July, 1900.
† *Phil. Mag.*, 1906, Vol. XI, p. 276, and Vol. XII, p. 418.

tension tests, and appears to be 36 000 lb. per sq. in. in tension, it really is 18 000 lb. per sq. in. in shear; and, under whatever condition of loading, simple or complex, when the shear reaches 18 000 lb. per sq. in., and not before, the elastic limit in this precise quality of steel will be reached.*

If steel or wrought iron should be pulled equally in all directions, there would be no shear, so that failure, if it occurred, would take place without any preliminary elastic limit; but there is no known way of making such a test.

Hydrostatic pressure, which, of course, is equal in all directions, has been applied to mild steel, wrought iron, cast iron, drawn brass, and drawn copper, in experiments at the Watertown Arsenal.† The pressure was estimated as 90 000 lb. per sq. in., except for one steel specimen for which it was 117 000 lb. per sq. in. The permanent effect of compression on the dimensions of the specimens was not appreciable with the steel, brass, and copper. The wrought iron and cast specimens after testing were smaller, but, as the reduction in dimensions did not take place uniformly, the effect was attributed to the closing of interstices formed by blow-holes, or the presence of cinder. A comparison of the results of tests shows no appreciable change in the strength, elasticity, and ductility of the compressed over the uncompressed metal.

The Beneficial Effects of Strain.

Between the temperatures at which iron and ordinary steel (containing less than 0.9% of carbon) are entirely liquid and the temperatures at which they are entirely solid there is a great range, for the major part of which the metal is technically a solid, because it requires stress exceeding a certain magnitude to produce continuous alteration of form. It does not follow, however, that the metal is all solid. It will answer the description of "plastic" if it consists of an intimate mixture of liquid and solid particles in which the solid particles are sufficiently connected to give the mass strength to resist a limited amount of shear. There are many plastic solids, such as putty, plaster, mud, and modeling clay, which are solid, according to

* This fact should be applied with caution. Quality varies, even within the same piece, and actual intensity is partly dependent on unknown initial internal stress; hence, the nominal stress intensity at which the elastic limit occurs is subject to variation in metal of nominally uniform quality.

† Report for 1886, pp. 1663, 1687.

the usual distinction between a viscous liquid and a plastic solid, but which, nevertheless, are part liquid and part solid. From the fact that changes take place in plastic iron and steel, within a certain range of temperature, which parallel those which take place in the viscous liquid state, it is highly probable that within this range the metal consists of an intimate mixture of solid particles, sufficiently connected to make the mass as a whole solid, and a highly viscous liquid which, like pitch, looks solid and adheres to the strictly solid portion. Be this as it may, a portion of the metal is a viscous liquid when it flows under pressure or pull.

According to metallurgists, as iron and steel with less than 0.9% of carbon slowly cool, the iron solidifies in first one and then another potentially hard, strong form containing carbon in solid solution, like sugar in gelatin, until a stage in the process of solidifying is reached, between 700 and 900° cent. (about 1 290 and 1 470° Fahr.), during which the iron expels the carbon and assumes a softer, weaker, pure form; the carbon combines with iron, forming cementite, Fe_3C, harder than glass and nearly as brittle, but probably very strong; the two substances minutely interstratify, in the proportion of six parts of iron to one part of cementite, and thus form a substance termed pearlite; and the pure iron and pearlite intimately mix. The changes at the end of this stage evolve so much heat that the mass is heated, and brightens in a striking manner. This phenomenon is called the "recalescence".

Slow cooling, through the stage at the end of which recalescence occurs, gives full opportunity for changes in the form of the iron and in the mixtures which result from the presence of carbon, and it facilitates the growth of crystals and of a coarse crystalline structure. These developments can be arrested or modified by hastening the complete solidification by sudden cooling, thereby producing in most cases a stronger steel than is obtained when the metal is allowed to cool slowly. The addition of certain elements, as in some of the alloy steels, will similarly arrest or modify the transformations.

It is not known to what extent steel or wrought iron made viscous by strain is similar in condition to the same metal at some high temperature, but it possesses one of the important characteristics of such hot metal—its sudden solidification makes for hardness and strength.

Structural steel and wrought iron during their manufacture are slowly cooled, undergo one or more reheatings, and are subject to mechanical force while cooling. The metal is an intimate mixture of particles which differ in their capacities to resist shear, though in most cases a considerable proportion forms a matrix which is nearly homogeneous in this respect and has disseminated throughout its mass the more or less connected stronger grains.

All structural steel and wrought iron, before the metal is strained in service or tests, contain in their free state some balanced initial internal shears produced by unequal cooling and the processes of manufacture. Therefore, when strained by an external load, the real intensity of the shear at any point is that of the apparent shear plus the initial internal shear. When this combined shear exceeds the shearing resistance of the metal, the latter becomes viscous and flows, thus relieving the initial internal shear, but causing a permanent set.

When, in such cases, the load is removed, the viscous metal resolidifies at a temperature far below its natural freezing point, and acquires thereby a very much greater shearing resistance, so that if, after a rest, a load in the same direction is again applied, the elasticity will be perfect up to the limit of the former loading. If the loading is carried beyond that limit, it will be some other portion of the metal not previously over-strained which will be the first to yield under the new loading.

In this way steel and wrought iron structural parts not subject to alternate stresses can have their elasticity perfected to the beginning of the general yield—the point known as the elastic limit. This conclusion agrees with Bauschinger's experiments, and harmonizes with the general trend of the experiments at the Watertown Arsenal; but the most satisfactory evidence of its substantial accuracy is the behavior of structures in service which, under frequently repeated and long continued heavy loads, give no evidence of any growth in permanent set so long as the strains are below the point at which the general yield would begin. It is possible that elasticity is similarly perfected to the same point in parts subjected to alternate stresses, but, for reasons explained in the next section—Fatigue—it is advisable to use, for such parts, a somewhat lower point as the criterion of permanent strength.

The elasticity can be perfected by over-straining, and the elastic limit raised thereby, even when the over-straining is carried beyond the original yield point; but this fact is of little practical importance to those structural members which are subjected primarily to direct tension or compression. The elongations and shortenings in such members are so great, after the yield point is reached, as to produce ruinous deformation in the structures of which such members are a part. In the case of compression members, unless they are very short, strain to the yield point means failure, as shown in Table 2.

The raising of the elastic limit by over-straining is of great use in manufacturing steel and wrought iron. It is this which gives to drawn wire, drawn steel, and cold-rolled steel their enhanced strength; and it is partly by over-straining that hot-forging and rolling raise the elastic limit of the metal; though part of the virtue of these operations on hot metal is due to refinement of crystalline structure and to the closing of cavities by bringing their sides to a welding contact. In all these manufacturing processes, to achieve good results, it is essential that the over-straining should not be too great, as explained in the next section—Fatigue.

When strains in steel and wrought iron are produced by transverse loading, there are special features by reason of which the effect of such strains requires separate consideration. These features are as follows:

First.—The distribution of stress, in cases of transverse loading, is too complicated a problem to admit of precise determination. The ordinary theory of flexure, even within the limits of perfect elasticity, is only an approximation.* It neglects the influence of distortion from shear on distribution of stress, and, in consequence, the stress in the extreme fiber is greater, so long as the elasticity is perfect, than the ordinary theory indicates. This is especially the case with short beams, having thin webs, under heavy concentrated loads.

Second.—The beginning of the general yield, as distinguished from imperfections in elasticity due to initial internal stresses, is not well marked.

* Professor A. E. H. Love on Elasticity, in Encyclopædia Britannica, 11th Ed., Vol. IX, pp. 141–160; also, Prichard on "Faults in the Theory of Flexure, and an Epitome of Certain I-Beam Tests made at Ambridge, Pa.", *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 895.

Third.—In consequence of the different distribution of stress, from that which obtains in cases of direct tension or compression, the progress and consequences of the yield are correspondingly different.

Consider the case of a horizontal round or square bar loaded vertically; when the load is such that stresses in the extreme fibers just equal the elastic limit, the intensity of the stresses will decrease nearly uniformly from the top and bottom toward a neutral axis at the center. When the load is increased, the elastic limit will be exceeded in some part of the extreme fibers, and they will become viscous and flow, thus relieving themselves of the stress in excess of such limit. The fibers immediately below the top and bottom ones will then be strained to their elastic limit, and the process will continue, when the load is sufficient, until, for quite a distance from the top and bottom of the bar, the metal at the critical portion of the span will be strained to its elastic limit and develop increased resistance accordingly. Moreover, the viscous metal will resolidify in stronger form. If the load is gradually taken off, the fibers toward the top and bottom will be entirely relieved of their stress before those nearer the center, after which tension will be developed in the top and compression in the bottom, forming a couple balanced by another and opposite couple nearer the axis; moreover, the bar will have a permanent deflection. If the load is again applied, the effect of taking off the load will be reversed, without any additional over-straining, unless the former load is exceeded. In this way, at the expense of a little permanent deflection, the strength of the bar to resist transverse loading in one direction can be greatly enhanced; but, if the direction of the load is reversed, the balanced internal stresses will tend to lower the elastic limit of the bar.

The principles explained in the foregoing paragraph apply to all cases of transverse loading, but, for beams, rolled or built, of I-section, the possibilities of enhancement of strength are not nearly as great as for those of round or square section, and may be offset by spreading the metal too thin.

Fatigue.

Fatigue, as applied to metals, is weakness produced by strain. It may be temporary or it may be permanent, and it may gradually increase under oft-repeated or long-continued stresses until it produces failure.

Structural steel and wrought iron made viscous by strain are extremely viscous; that is, their flow under stress is exceedingly slow. For instance, a wrought-iron bar, 1 in. square, tested as a horizontal beam, which had been made partly viscous by a gradually increasing center load during 8 days, was then loaded at the center with 2 589 lb. Under this load its deflection gradually increased during 61.5 hours from 4.2749 to 4.6701 in., at which point the weights reached the support and the test was discontinued.*

When a bar of structural steel or wrought iron is strained beyond its elastic limit, it becomes an intimate mixture of viscous liquid and elastic solid portions. After the load which produced the strain is removed, the solid elastic portion endeavors to resume its former size and shape, and would do so almost instantly were it not for the opposition of the viscous liquid which adheres to it and is compelled thereby to flow, but which refuses to flow rapidly and, in consequence, is for a while subjected to a push or pull from the elastic solid portion, the return of which to its former size and shape is thus delayed.

The viscous portion of over-strained steel and iron may solidify even while the piece of which it is a portion is subjected to stress. For instance, the 1-in. square bar just referred to was loaded in the center, at one stage of the experiment, with 1 600 lb., and while thus loaded its deflection gradually increased during 16 min. from 0.489 to 0.6598 in., but then the viscous metal appears to have solidified, as there was no further deflection during the remainder of the 5 hours and 44 min. that the load remained unchanged.

Just as there is, for each elementary portion of structural steel and wrought iron at atmospheric temperature, a certain intensity of shear beyond which solid metal becomes viscous, so there is a certain intensity of shear beyond which viscous metal subjected thereto remains viscous and flows; but when the flowing releases the viscous metal from shear in excess of the critical intensity, it will resolidify. In cases where iron and steel have been strained to a point below that at which the general yield commences, but at which, by reason of initial internal stresses, a small portion of the metal has become viscous, the recoil of the large elastic solid portion on release of stress will act on the

* Report of U. S. Board on Testing Iron and Steel, Vol. 1, pp. 464, 469, and 471 (1881).

viscous portion, but with such low intensity and through such a short distance that it will not prevent rapid solidification.

On the other hand, in cases where the yield point has been somewhat exceeded, the stress intensity in the elastic solid portion of the metal will be very high, and, on the release of the stress, this solid portion, in its endeavor to regain its former size and shape, will push or pull some part of the viscous portion, causing it to remain viscous and slowly flow while the solid portion gradually recoils. This process will continue until the intensity of the shear resulting from the push or pull is reduced to a point below that required to prevent the solidification of the viscous portion.

Much of the recovery after over-strain takes place in a few minutes, and nearly all in a few hours; but, toward the very end, as the force from the recoil of the elastic solid portion of the metal approaches the intensity permitting complete solidification, the process becomes exceedingly slow, and may continue for many days. At this stage, it appears, from experiments by Mr. J. Muir, that the shear exceeds the resistance of the viscous portion of the metal to flowing by such a narrow margin that the changes incident to a slight increase in temperature will turn the scale. He found that pieces of medium steel which normally required a long rest to recover their elasticity at atmospheric temperature, after being over-strained in tension, recovered it in a few minutes when exposed to the temperature of boiling water.*

Straining metals beyond their elastic limit and thus causing them to flow, as explained in the section on Shear, implies a rotation of one group of solid elements through a definite angle with respect to another group of such elements. This tends to create minute interstices between solid elements. These interstices have to be filled with viscous metal to act as cement, or there will be cavities and cracks. If iron or steel is not very ductile, so that only a small portion becomes viscous under high stress intensity, or if it is ductile but so overstrained that the viscous portion will not fill the interstices, the overstraining will develop permanent cavities and cracks which nothing but heating will remedy. In fact, iron and steel can be strained, even when at welding heat, to an extent which develops flaws which nothing short of remelting can remedy.

* Muir "On Recovery of Iron from Overstrain", *Phil. Trans.* A, Vol. 193, (1910).

With respect to strain, hot steel (or hot wrought iron) differs from cold steel (or cold wrought iron) in having a lower elastic limit, in offering less resistance to deformation under stresses in excess of the elastic limit, and in affording opportunity for heat treatment and welding while being over-strained. It is possible that some of the alloy steels owe their good qualities in part to an influence in the hot metal whereby it permits and receives greater over-straining under good welding conditions than in ordinary steel.

Blow-holes, foreign substances (such as sulphide of iron and graphite), and cavities and cracks, caused by over-straining while cold or hot, break the continuity of the metal and thereby weaken it. Probably no steel or iron is free from such flaws, though in metal of good quality it requires a microscopical examination to discover them. These breaks in the continuity of the metal cause the stress to be concentrated at their edges, and it is in this way, much more than by reducing the effective cross-sectional area, that these flaws weaken the metal in which they occur.

It is common experience that the easiest way to break a small piece of metal is to bend it alternately backward and forward. Similarly, by straining bars alternately in tension and compression, as in a rotating shaft, a small crack can be extended by stresses locally until it becomes a plane of rupture without much preliminary evidence of a general yield.

"In experiments by Ewing and J. C. W. Humfrey ('The Fracture of Metals under repeated Alternations of Stress,' *Phil. Trans.*, 1903) the microscope was employed to examine the process by which metals break through 'fatigue' when subjected to repeated reversals of stress. The test-pieces were short rods overhanging from a revolving mandrel and loaded at the end so as to produce a bending moment. A part near the support, where the stresses due to bending were greatest, was polished beforehand for observation in the microscope. After a certain number of reversals the surface was examined, and the examination was repeated at intervals as the process continued. The material was Swedish iron following Hooke's law (in tension) up to 13 tons per sq. in. and having a well-marked yield-point at 14.1 tons per sq. in. It was found that the material suffered no damage from repeated reversals of a stress of 5 tons per sq. in., but that when the greatest stress was raised to 7 tons per sq. in. incipient signs of fatigue began to be apparent after many reversals, though the piece was still intact after the number of reversals had reached three millions. With

a stress of 9 tons per sq. in., or more, repeated reversals brought about fracture. The first sign of fatigue as detected in the microscope was that slip lines began to appear on one or more of the crystals in the region of greatest stress: as the process went on these became more distinct and tended to broaden, and at length some of them developed into cracks which were identified as such because they did not disappear when the surface was repolished. Once a crack had formed it quickly spread, and finally the piece broke with a sharp fracture, showing practically no plastic change of form before rupture."*

Probably the most extensive series of experiments with rotating shafts were made at the Watertown Arsenal during a period of ten or more years prior to 1908. A synopsis of some of these experiments—a great many tests of hot-rolled open-hearth steel bars—is given in Table 3. It is interesting to note that in one case the fracture started from a slight indentation and in another case from a slight scratch on the surface of the shaft. With the exception of 0.73% carbon steel, the pulling tests showed well-marked yield points, either at the elastic limit or very slightly above. The results of pulling tests from ruptured bars agreed substantially with those of the auxiliary pulling tests, except for a slight decrease in elongation. The 1.09% carbon steel failed under alternating stresses of an intensity 51.9% of the elastic limit. Omitting this steel from consideration, on account of its being much higher in carbon than steel used for structures, the lowest intensity, relative to the elastic limit, at which the steel failed in these endurance tests was 61.4% of that limit. The extreme intensities of the alternating stresses recorded in these tests were computed for static conditions, in accordance with the theory of flexure; but, as this theory gives results which, when the elastic limit is not exceeded, are too low, and as the shafts were rotating 500 times per min., the actual extreme intensities and their ratios to the elastic limit were, probably, somewhat greater than are given in the table.

An extensive set of experiments was made "On Resistance of Iron and Steel to Reversals of Direct Stress" by Thomas Ernest Stanton and Leonard Bairstow.† The specimens they used were tested by direct instead of bending stress. Table 4 gives the results of the critical tests, that is, those in which rupture occurred at the least

intensity of stress, and those which endured the greatest number of reversals of stress without rupture. In these tests, as in those described by Ewing, microscopical examination during their progress showed that failure was caused by the gradual development of cracks.

The tests recorded in Tables 3 and 4 have a direct bearing on the strength of moving parts of machinery. As regards wrought-iron and steel structures, although the conditions are not precisely analogous, it may be inferred that a somewhat similar fatigue would occur, in those parts which are subjected to frequent alternations of stress, if certain limits less than the elastic limit were exceeded. In structural

TABLE 4.—Resistance of Iron and Steel to Reversals of Direct Stress.

Compiled from Stanton and Bairstow's paper in *Minutes of Proceedings*, Inst. C. E., Vol. CLXVI, 1906, Part IV.

Stresses were direct and produced by a periodic motion, about 800 cycles per minute, of a reciprocating mass by means of a connecting rod, the specimen under test forming the link between the reciprocating mass and the cross-head.

The ratio of tension to compression was: for Items 1 to 18, 1.4; for Items 19 to 22, 1.09; for Items 23 and 24, 0.92; for Items 25 to 27, 0.72.

Item 19 was one of a set which the authors believed to be subject to some secondary effect, to avoid which they made test pieces somewhat smaller for set including Items 20 to 22.

All stresses are in tons per square inch.

members, however, as the frequency of the alternations is much less than in these tests, and as periods of rest are interspersed between alternations, it is fair to assume that the limits between which the stresses can alternate are greater than in the tests. It is a fair inference from the tests cited that stress of great intensity in tension or compression reduces the capacity of a structural member to resist immediately, without injury, stress of the opposite kind, but not to the extent indicated in Tables 3 and 4.

In the case of a member subject to alternate tension and compression of equal intensity, if the capacity of the steel to resist either stress were reduced to two-thirds of what it would be to resist one or the other without any alternations, the effect on the sectional area required would be equivalent to that of a 50% increase in the total stress in a member subject to only one kind of stress; and the ratio

of the range of stress (that is, tension plus compression) to the capacity of the metal when there are no alternations of stress to resist without injury either kind, would be twice two-thirds or 1.333. When this ratio is compared with the ratios of range of stress to elastic limit given in Table 4, in the light of the differences in conditions, the assumption from which it was derived seems reasonably safe. The proportion chosen for this tentative assumption was such as gives, when the alternate stresses are equal, some basis of comparison of Table 4 with the provision for alternating stresses given in the American Railway Engineering Association's General Specifications for Steel Railway Bridges. This provision, taken from the third edition (1910), Paragraph 22, is as follows:

"Members subject to alternate stresses of tension and compression shall be proportioned for the stresses giving the largest section. If the alternate stresses occur in succession during the passage of one train, as in stiff counters, each stress shall be increased by 50 per cent. of the smaller. The connections shall in all cases be proportioned for the sum of the stresses."

In certain conditions, some of the fatigue under alternating stresses within the elastic limit is temporary. Lord Kelvin and other experimenters have observed such a fatigue in vibrating wires. Wires which had been kept vibrating for several hours or days, within certain limits much below the elastic limit, came to a rest much sooner when left to themselves than when set in vibration after they had been at rest for several days and were then immediately left to themselves. This may have been due to initial internal stresses which, in combination with stresses from the external forces, over-strained small portions of the metal and made them viscous. The rapid vibration of the wires may then have prevented the viscous metal from solidifying, and gradually increased the fatigue. During a rest, the viscous portion of the metal would resolidify, and new internal stresses would be developed, as previously explained in discussing flexure.

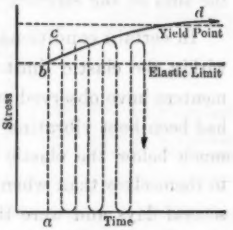
It is a matter of experience that, when there are bad faults in steel or wrought iron, failure may occur under stresses (which are repeated or continued) of computed intensity less than the elastic limit, with little prior warning in the way of deformation. It is conceivable that failure of steel and wrought iron from fatigue might similarly occur under repeated or continued stresses within the elastic limit,

even when the initial flaws are microscopic; but there is nothing in experience or tests to cause fear of such a result when the material is of good quality and the stresses are not reversed. Of course, failure may occur in compression from slenderness under stresses within the elastic limit, but this has nothing to do with fatigue.

The most thorough, scientific, and valuable experimental investigation of repeated stresses in steel and wrought iron was made by the late Professor Johann Bauschinger. In these experiments he used a remarkable measuring device which was sensitive to $\frac{1}{10\,000}$ mm. (about $\frac{1}{250\,000}$ in.), and the repetitions of stress ranged from 5 000 000 to 10 000 000, or more.

The results of this profound investigation by this noted scientist were published in 1886,* and were well epitomized by Professor W. C. Unwin in discussing Stanton and Bairstow's paper on reversals of stress, as follows:

"Bauschinger was the first to notice the remarkable variation of the position of the true limit of elasticity—not the yield-point, but the limit of proportionality—when a bar was subjected to straining actions. The important Paper which he wrote in 1885 dealt almost wholly with the effect of variations of tensile stress, and the point which Bauschinger fully made out was illustrated diagrammatically by Fig. 38.† Suppose a bar subjected to a stress varying between 0 and a limit *c* above the real primitive elastic limit. The successive applications of the stress were shown by the dotted line. The elastic limit initially at *b* would rise sometimes above the primitive yield-point as shown by the strong line *b d*. Now if *d* was above the applied stress *c*, no number of repetitions of stress would break the bar. But if *c* was above *d*, the point to which the elastic limit rose, then the bar would break after a certain number of repetitions of stress. That was for variation of stress in one direction, and he thought it was something more than a mere theory, and that the point had been completely made out."



(Unwin's Fig. 38)
FIG. 6.

It is evident that when the stresses are not reversed the elastic limit of steel and wrought iron in structures is the criterion of safety with respect to stress intensity, and that the real factor of safety in

* Communication No. 13, Testing Laboratory, School of Technology of Munich.
† Reproduced herein as Fig. 6.

such cases is the ratio of the elastic limit to the actual stress, instead of the ratio of the momentary ultimate strength to the actual stress.

For steel and wrought-iron railway bridges, when the actual stresses in members subjected to only one kind of stress are within the elastic limit, and when the actual stresses in members subjected to alternate stresses are within two-thirds of said limit, it is reasonable to assume that the life of these structures will depend on other considerations. Although experiments do not warrant the conclusion that steel and wrought iron can resist endless repetitions of stress to those limits, neither do they warrant the conclusion that these metals cannot do so; and both experiments and experience indicate that steel and wrought iron in bridges can resist to these limits for so long a period that the resistance may for practical purposes be considered permanent. This, of course, does not mean that a structure is necessarily safe if the computed stresses are within the supposed elastic limit (or two-thirds thereof if the stress alternates); for the real stresses may be greater than computed and the actual elastic limit less than supposed, and the compression members may be lacking in stiffness and the structure unstable.

The fatigue or weakening of a piece of steel or wrought iron which occurs when it is strained in tension and compression alternately beyond certain limits (which are often well within the elastic limit) makes it subject to sudden fracture, without much preliminary deformation; similarly, as in a piece in which the crystals or grains have united in regular crystalline formation without much mechanical interference from hot-forging, rolling, or pressing; hence such weakening is often called crystallizing, and by some is actually conceived to be a phenomenon in crystallogeny—an idea fostered by the fact that the crystals or grains of which steel and wrought iron are composed are displayed in sudden fractures but are more or less disguised in ordinary tests for quality by being drawn out before they are broken.

There is probably no change, in the structure of metals, from strain, so long as no part is over-strained. When metals are made partly viscous by over-straining and are then allowed to resolidify, the resolidified portion, of course, has a new structure. In lead, according to Ewing, severe over-straining is followed, even at atmospheric temperatures, by a protracted crystalline growth which results in the

formation of crystals which are relatively very large.* There is no evidence, however, that steel and wrought iron made viscous by over-straining resolidify in large crystals at atmospheric temperatures. Atmospheric temperatures are so far below the recalescence point of steel and iron that it seems reasonable to expect that the viscous metal at such temperatures will not resolidify in large crystals. There is, in fact, considerable to indicate that films of steel made viscous by over-straining will, after resolidification, be in an amorphous condition; that is, not crystallized, even in the minutest particles. It would seem that the solidification is, in the main, so rapid that the crystals do not have time in which to grow to discernible size.†

Launhardt's Fatigue Formula.

As has been shown, the elastic limit of structural steel and wrought iron can be raised by over-straining followed by a rest. Experiments by Wöhler during the period 1858-1870 indicate that it can also be raised when part of the stress is constant and part is constantly repeated, even without intervals of rest, and seem to indicate that the amount by which it can be raised increases with the proportion of constant stress. The phrase "seem to indicate" is used deliberately,

* Encyclopædia Britannica, 11th Ed., Vol. XXV, p. 1018.

† "About ten years ago [dating from May, 1911] the microscopic study of the structure and behavior of metal led to the discovery of the true nature of the operation of polishing. In this operation a true skin is formed over the polished surface. This skin gives unmistakable signs that it has passed through a state in which it must have possessed the perfect mobility of a liquid. In its final state it possesses distinctive qualities which differentiate its substance very clearly from that of the unaltered substance beneath it. It is, for instance, much harder and, even when formed on the face of a crystal on which the hardness varies in different directions, its hardness is the same in all directions. * * * The discovery that layers of a solid many hundreds of molecules in thickness can have a mobility of the liquid state conferred on them by purely mechanical movement, opened up a new field of inquiry into internal structure of metals which have been hardened by cold working. As a result of this inquiry a theory of the hard and soft states was suggested. According to this theory, hardening results from the formation at all the internal surfaces of slip or shear of mobile layers similar to those produced on the outer surface by polishing. These layers only retain their mobility for a very brief period and then solidify in a vitreous amorphous state, thus cementing material at all surfaces of slip or shear throughout the mass. * * *

"The ductile metals, when pure, do not pass into a vitreous amorphous state by cooling, because their molecules retain the power of crystalline rearrangement over a very long range of temperature below the solidifying point. Gold solidifies at 1080° and its minimum crystallizing temperature is somewhere about 230°. There is thus a range of about 800° over which crystallization can occur. It is obvious that no ordinary method of chilling could carry a mass of metal over this long range so quickly that it could not crystallize. Though the arrest of crystallization by chilling the molten metal is practically impossible, this arrest can and does occur in the thin layers of mobile molecules which are produced by mechanical flow. The evidence from observations which have extended over nearly ten years has made it certain that metals can exist in the vitreous amorphous form, and that the recrystallization which occurs when the point of thermal instability is reached is strictly analogous to the similar phenomenon which occurs when other well-known vitreous substances are kept at a suitable temperature in the presence of crystalline nucleus." From "1911 May Lecture", by G. T. Beilby, LL.D., F. R. S. (Member of Council) on "The Hard and Soft State in Metals", published in the *Journal* of the Institute of Metals, Vol. VI. pp. 5, 6, and 9.

for the reasons that the experiments in which the stress was produced by direct pull were meager and inconclusive, and the nominal stresses recorded in the extensive bending tests were computed by the ordinary theory of flexure, which is not even approximately correct when the elastic limit is exceeded.

Following Wöhler's experiments, Launhardt devised what is known as a fatigue formula, which is supposed to indicate the farthest point to which the stresses can be carried just to avoid failures from fatigue under various proportions of constant and constantly repeated stresses.

Launhardt's formula, as given by Weyrauch for wrought iron, is

$$a = u\left(1 + \frac{1}{2}\frac{\text{Minimum stress}}{\text{Maximum stress}}\right) \quad \ldots\ldots\ldots\ldots (1)$$

where

a = ultimate working strength per unit of section under the conditions assumed,

u = ultimate strength per unit of section for any number of repetitions of load.

In Wöhler's tests, a bar repeatedly pulled from 0 to 320 centners per square zoll, finally ruptured on the 10 141 645th application of the stress.

320 centners per square zoll is a little more than 30 000 lb. per sq. in.*

Adopting the square inch and the pound as units, and taking the value of u as 30 000, the Weyrauch-Launhardt formula for wrought iron becomes:

$$a = 30\,000\left(1 + \frac{1}{2}\frac{\text{Minimum stress}}{\text{Maximum stress}}\right) \quad \ldots\ldots\ldots\ldots (2)$$

According to this formula, the greatest stress per square inch to which wrought iron can be subjected without permanent fatigue varies from 30 000 lb., in cases where all the stress is constantly repeated, to 45 000 lb., in cases where it is all constant.

As even 30 000 lb. is above the elastic limit of ordinary wrought iron, such metal would have to have its elastic limit raised somewhat more than 50% by over-straining before it could stand permanently 45 000 lb. per sq. in.

It is not reasonable to apply this and similar formulas to the design of bridges, because two of the fundamental considerations on which such formulas rest are not realized in these structures: the

* According to Bauschinger (*loc. cit.*, p. 44), the centner per square zoll in which Wöhler gives his results in equivalent to 6.837 kg. per sq. cm., or 972 lb. per sq. in.

stresses are not constantly repeated without intervals of rest; and the permanent strength cannot possibly be increased, in non-adjustable tension and compression members, far above the primitive elastic limit, for the reason that the change in length of such members when strained beyond the yield point is so great as to be ruinous. After once being strained a little beyond the yield point, there would be no repeated stresses. It is quite probable, however, that, at the expense of some undesirable though not ruinous distortion of a structure, its tension members and very short compression members could have their elastic limit and practically permanent strength raised nearly to the yield point.

A considerable number of American engineers use a formula, in appearance greatly resembling Launhardt's, which evaluates the permissible working stress per square inch with quantities intended to give a constant factor of safety, with respect to the capacity of the metal just to avoid permanent fatigue, and at the same time allow for impact. As an illustration, the following formula is quoted, from the specifications of a large railway system, for permissible tension per square inch.

$$\text{Tension, rolled bars, } = 7\,500\left(1+\frac{\text{Minimum stress}}{\text{Maximum stress}}\right) \ldots\ldots (3)$$

In explaining this formula, the capacity of the metal just to avoid permanent fatigue is assumed to be a function of the maximum permissible stress (from 7 500 to 15 000 lb. per sq. in.), instead of a function of the maximum permanent strength (from 30 000 to 45 000 lb. per sq. in., according to the minimum); a modification for which, as far as the experiments or theories regarding fatigue are concerned, there is no warrant.

Some engineers, who realize that Formula (3) is wholly unsound with respect to the possibilities of fatigue in bridges, continue to use it, on the ground that it makes a good provision for impact. Those who advocate it solely as a provision for impact should use an equivalent method of making such provision, which clearly defines their position, is much more convenient, and brings precisely the same sectional area, as follows:

$$\text{Impact} = \text{live load}\left(\frac{\text{Maximum stress}}{\text{Maximum stress} + \text{minimum stress}}\right) \ldots (4)$$

Permissible tension in rolled bars = 15 000 lb. per sq. in.

The chief objection to formulas such as (3) and (4) is that, for long-span bridges, they make the provision for dead load relatively too small as compared with the provision for live load; which may be dangerous when the permissible unit stress is high and the dead load predominates.

In the case of bending stresses, either by themselves or in combination with direct tension or compression, there is some opportunity for enhancement of the elastic limit, without serious distortion, under constant stresses or repeated stresses in one direction, especially in solid members such as pins; but, in the case of bending stresses in combination with direct compression, the opportunity is quite limited.

Acknowledgment is made of valuable suggestions from C. E. Chase, Jun. Am. Soc. C. E., who kindly made a critical review of the paper in its preliminary form.

DISCUSSION

Mr. Waddell.

J. A. L. WADDELL,* M. AM. SOC. C. E. (by letter).—This paper is exceedingly interesting and valuable, for these two reasons:

First.—The author has given to the Engineering Profession in concise form a history and a complete explanation of the phenomenon known as "the fatigue of metals".

Second.—He has shown that, as far as modern bridge designing is concerned, the fatigue of steel is a matter that can, with the utmost propriety, be totally ignored.

Ever since bridge designing began to become truly a science—about a quarter of a century ago—the writer has maintained that the fatigue of metal has no application whatsoever in the proper proportioning of bridge members. Judging from the character of modern bridge specifications, most of the authorities now agree with him; but a few still use formulas which are based, either directly or indirectly, on the fatigue theory; and intelligent laymen are prone to talk about the crystallization of steel in bridges—something which does not exist and never did exist, even in the old days of inadequately proportioned railroad structures. Consequently, it is very gratifying to the writer to see how effectively Mr. Prichard has exposed the fallacy which for many years gave to bridge computers so much extra labor which was totally unnecessary and valueless.

For non-reversing stresses, Mr. Prichard points out that, even with wrought iron, under the worst possible circumstances, the actual intensity of working stress must be as great as 30 000 lb. in order to produce any fatigue that will ultimately result in rupture; and as the weakest bridge steel is fully 20% stronger than wrought iron, the corresponding limit for that metal would be 36 000 lb. Now, as modern bridge specifications stress medium-carbon steel up to only 16 000 lb. per sq. in. for the usual loadings when the effect of impact is included, it is evident that the factor of safety is about 2.25. It is true that, when the greatest possible wind-load stresses are combined with the maximum live, impact, and dead-load stresses, it is permissible to stress the metal 30% higher, or to 20 800 lb. per sq. in., which would reduce the factor of safety to 1.73; but this is practically an impossible loading; hence it may be concluded that, as far as fatigue without stress reversal is concerned, modern bridges have a factor of safety of about 2. This is used so as to cover the possibility of small imperfections existing in the metal; and it is an ample allowance for that and all other considerations.

For the case of reversing stresses, however, it is not quite so evident as it is in the case of non-reversing stresses that the effect of

* Kansas City, Mo.

Mr. Waddell.

fatigue can be entirely ignored; hence a simple computation will be made to prove it.

In the first place, it should be stated that for ordinary bridges the members subjected to alternating stresses are not affected by wind, hence the excess percentage for intensities with wind-load combinations need not be considered. The writer's latest specifications for the effect of reversing stresses provide that when the reversion comes from a single live loading, the sectional area of any piece is to be computed by adding to the maximum tension 75% of the maximum compression and dividing the sum by 16 000; also, by adding to the maximum compression 75% of the maximum tension and dividing the sum by $16\,000 - a\frac{l}{r}$, where a is equal to 60 for riveted construction or 80 for pin-connected construction. In case the reversion is produced by some other live loadings, the same method is to be followed, except that 50% instead of 75% is to be added. The larger of the two areas thus obtained is, of course, the one to be adopted.

The worst case of reversion that can be found in ordinary bridge designing is that of the web diagonal at the foot of the middle vertical post in a very long-span, simple-truss bridge having an even number of double panels. If it is assumed that the live-load tensile stress on the diagonal, including impact, is 700 000 lb., the dead-load tension thereon will be about 100 000 lb., and the live-load compression (including impact) about 570 000 lb.

Proportioning for tension, we have:

$$A = \frac{750\,000 + 100\,000 + 0.75 \times 570\,000}{16\,000} = 76.7 \text{ sq. in.}$$

Adding 20% for rivet-holes makes 92 sq. in.

Proportioning for compression, assuming that $\frac{l}{r} = 50$, and that the truss is pin-connected, we have:

$$A = \frac{570\,000 - 100\,000 + 0.75 \times 700\,000}{12\,000} = 83 \text{ sq. in.}$$

It is seen, therefore, that it is the tension which counts; and, consequently, the maximum actual intensity on the net section will be

$$\frac{700\,000 + 100\,000}{76.7} = 10\,400 \text{ lb., nearly.}$$

The elastic limit for medium bridge steel is 35 000 lb. per sq. in., and, as the worst case of percentage for fatigue of such steel given in Tables 3 and 4 may be taken as not exceeding 60, the safe limit for reversion would be $35\,000 \times 0.6 = 21\,000$ lb., or almost exactly twice

Mr. Waddell. the actual intensity just found for the most unfavorable condition of stress reversion.

From these rough figures it is safe to conclude that, as far as the old bugbear of fatigue of metal is concerned, modern steel bridges will have a factor of safety of 2 after the effects of impact from live load have been included.

Mr. Prichard's paper certainly ought to put an effective stop to any further talk among engineers concerning fatigue of metal in steel structures, and to expressions of dread from educated laymen about the danger to the traveling public from crystallization of metal in bridges. If such a result is attained, Mr. Prichard will truly deserve the hearty thanks, not only of the Engineering Profession, but also of people in general, for his exhaustive and masterly memoir.

Mr. Seaman. HENRY B. SEAMAN,* M. AM. SOC. C. E. (by letter).—In referring to the use of the Launhardt formula for bridge design, Mr. Prichard states:

"It is not reasonable to apply this and similar formulas to the design of bridges, because two of the fundamental considerations on which such formulas rest are not realized in these structures, * * *."

The writer, however, would call attention to the fact that objections to the use of the Launhardt formula rest on much broader grounds, namely, the formula itself is not justified, either in its manner of deduction, or in the tests on which it rests. This was discussed fully before the Society in 1899.†

Mr. Turner. C. A. P. TURNER,‡ M. AM. SOC. C. E. (by letter).—This paper again brings up for discussion the maximum and minimum formulas which have largely disappeared from bridge specifications to-day. These formulas are based on the assumption that there is some direct relation between detrimental effects of high and low stresses, some of these stresses being below the so-called elastic limit of the metal. The elastic limit is determined commercially by the drop of the beam; but, in more precise tests, the extensometer is used and the set noted. The degree of elasticity thus determined, however, even when there is no set or deformation, does not determine the true elastic limit, because some of the work applied to the bar in stretching it may not be given back in its return to its original form during removal of the load, so that it would take a very delicate apparatus indeed to determine what is going on within the bar. In general, it is known that every set or permanent distortion is accompanied by heat. It is

* New York City.

† "The Launhardt Formula, and Railroad Bridge Specifications", *Transactions*, Am. Soc. C. E., Vol. XLI, p. 140.

‡ Minneapolis, Minn.

known that the bar grows colder as it is stretched, until some set takes place. Mr. Turner.

By delicate thermo-electric means,* it is possible to determine what is going on within a bar and how far that bar may be stretched without the evolution of heat accompanying either deformation or disturbance of the internal structure. These limits, as determined approximately by thermo-electric measurement, seem to be the same as those within which Bauschinger concludes that, unless there are flaws, range of stress improves the elasticity, ductility, and tenacity of the specimen. In other words, within this range of true elasticity, there is no such thing as fatigue, which later may be defined as a change in the structure of the bar brought about by excessive stress. If the viewpoint be in fact that just outlined, then fatigue formulas have no place in the proper design of bridge structures in which the intention is to keep stresses within such well-defined limits that overstrain does not occur. Over-confidence in the logical foundation of maximum and minimum formulas seems to have been responsible, in part at least, for the high stresses allowed in portions of the ill-fated Quebec Bridge. More uniform working stresses, with a slight improvement in the make-up of the sections, would undoubtedly have prevented this unfortunate failure. The acceptance by some of maximum and minimum formulas seems to have arisen, not from the teaching of experience in bridge construction, but rather on account of their plausibility from an algebraic standpoint and a disregard of any precise distinction between true and approximate values of the elastic limit.

T. D. Lynch,† Assoc. M. Am. Soc. C. E. (by letter).—The writer's experience has shown that very few engineers realize how low the true elastic limit really is in untreated or annealed structural steel. Mr. Lynch.

Plates having a tensile strength of more than 60 000 lb. per sq. in. may, and often do, have a true elastic limit of 15 000 lb. per sq. in. or less, and the fact that it has been customary to use a large factor of safety is the only excuse many structures have for not falling.

As engineering progresses toward economical production, and designers work to closer and closer limits, it is necessary to study more carefully the real characteristics of the material used.

This has been found to be true in the manufacture of heavy machinery, and structural engineers will find it equally true in making safe their great constructions of bridges and buildings. Those who are working to the "yield point" as taken by the drop of beam will find on final analysis that it means practically nothing unless used as indicative of the material's real value as having been determined by special tests to represent each class of material—untreated, heat-treated, or annealed.

* *Transactions*, Am. Soc. C. E., Vol. XLVIII, p. 140.

† Wilkinsburg, Pa.

Mr. Lynch. The writer is pleased to refer any member who may wish to examine this subject further to two papers* presented by him before the American Society for Testing Materials.

There seem to be two fundamentals that must not be overlooked, although in many cases research work may be necessary to determine them:

First.—Study stresses to know what they are.

Second.—Study the characteristics of the steel to be used; determine its true elastic limit; and keep below it.

These two fundamentals can but insure safety of construction.

Mr. Howard. JAMES E. HOWARD,† ESQ. (by letter).—Mr. Prichard presents a paper on the physics of iron and steel, which is of exceptional interest; its scope, if amplified, would constitute a treatise on the fundamental properties of structural materials.

It can hardly have escaped notice that a tendency has displayed itself recently to overlook some of the basic and underlying features which govern the physical properties of metals; and, in the examination of iron and steel, tests are multiplied, giving them considerable diversity without having scientific ends in view, and not attaining results of direct application to the conditions which prevail in the use of constructive materials.

On account of the attention which is given to the principles on which engineering practice in the use of steel should rest, and other reasons which are equally conspicuous, this paper possesses interest of unusual degree.

In the different places in which steels are used, the requirements vary, and metal suitable to meet these varied needs must be regulated according to the demands which are present. The properties of the materials should bear a definite relation to service requirements. This calls for a proper selection of metal in each case and a careful discrimination as to what constitutes the important factors, in order to promote durability under working conditions.

There are limitations in respect to the ability of all grades of steel to endure stresses. Steels of different composition have, in their primitive annealed states, definite limits of endurance, the maximum utilization of which is influenced by the manner in which they are loaded. In an unannealed state, or after having been subjected to heat or mechanical treatment, their properties are materially modified. It is desirable to ascertain the influence which different states of the steel have on its endurance for varying conditions of service. The

† Washington, D. C.

Mr. Howard.

initial properties easily admit of modification, which the tests of the metal clearly show; nevertheless, it is not always certain what ultimate or permanent advantages accrue from the possession of these modified properties. This information must be acquired through special experimental inquiry or as the result of long exposure under service conditions.

It is desirable to ascertain what features, in the initial properties, are indexical of those which contribute toward final durability.

Establishing the value of the elastic limit is early brought to notice when determining the physical properties of steel. It would seem that very little difficulty should be encountered in agreeing on what constitutes this factor, whether for research or for commercial purposes. Experience with metals has been ample to establish the fact, at least within limits of practical importance, that the modulus of elasticity of steel has a constant value within the limits of over-straining forces, that is, until a decided permanent set has been given the metal.

This being the case, the stress-strain curve is necessarily a straight line up to the load which causes a permanent set. The departure of the curve from a straight line, therefore, must indicate that a permanent set has been given the steel. It does not appear necessary to release the load during testing to confirm such an indication.

In a general way, these remarks comprise the principal statement which need be made in reference to defining the elastic limit of steel. Whether there is or is not a well-defined elastic limit in a given piece of steel, due to composition or treatment, and what degree of responsibility attaches to the manipulation of the test in obscuring that limit, are matters to be considered, but do not constitute a part of the main question.

Sharpness of definition of the elastic limit depends on the grade of steel, and on its state of initial strain. Concerning initial strains, they are affected by the manipulation of the steel and by incidents connected with its manufacture.

In the milder grades, jogs appear in the stress-strain curves, the metal displaying considerable elongation without increase of load, or under slightly diminished stresses. Jogs also appear when the metal is moderately heated, and disappear when higher temperatures are reached. Reversal of stress, from compression to tension—each being an over-straining load—removes the tendency to display a jog in the curve just beyond the elastic limit. The harder steels do not display jogs.

Initial strains obscure the sharpness of the elastic limit and tend to render its position vague. Initial strains may be acquired by a rapid rate of cooling during manufacture, and may result also from subsequent mechanical treatment, that is, from cold-working. Initial strains

Mr. Howard.

will be of two kinds, tension and compression, in order to maintain a state of equilibrium. The magnitude of one or both may at times reach and coincide with the elastic limit in those parts of the bar in which they exist.

An external force required to cause a permanent set will be the difference between the real elastic limit of the steel and the initial strain present which has the same algebraic sign as the external force. If internal initial strains coincide with the elastic limit, then any external force, however small, will cause a permanent set. Initial strains vary in their intensity in different parts of the cross-section of the bar, whence it follows that an external force gradually increased causes a progressive development of permanent sets. Local sets gradually extend to other parts of the cross-section, as external loads are increased, until the metal is in a state of over-strain throughout.

All rolled structural shapes acquire initial strains during fabrication, and these shapes necessarily display early local sets when loaded either by tension or by compression. The influence of such strains is particularly felt in tests on the ultimate strength of compression members. Initial strains, corresponding to many thousand pounds per square inch, residing in the component parts of built-up columns, and not given due consideration, necessarily tend to render futile all efforts to establish formulas for long columns.

Until loads are reached which cause sets to appear, the rate of extension or compression is not affected by the presence of initial strains in the steel. If the working stresses are low, the initial strains will pass unnoticed in structural members. It can hardly be said that the metal has no elastic limit when perchance initial strains exist in such degree that local sets are displayed under the earliest increments of load.

The effects of eccentricity in loading in the testing machine are similar to those caused by initial strains, in respect to the development of early sets. Relative to this matter, a prolific source of error is recognized which attaches to the manipulation of tests. Extensometer readings, of which the following are recent examples, showed measurements on three elements of a test piece, 120° apart, in which the stresses corresponding to the strains reported were 12 000, 15 000, and 18 000 lb. per sq. in., respectively. That is, the strain on one element was one and one-half times that on another. Early and progressive sets must necessarily have been developed on the side of the test piece which was strained so much in excess of that of the shorter side.

The modulus of elasticity is disturbed in over-strained steel, and temporarily has a lower value than normal. Temporarily, at least, it also has a variable value in over-strained steel. The reduction in value, however, is not of so pronounced a degree as to obscure the limit at which permanent sets are first acquired.

Mr. Howard.

A number of terms have been proposed in current technical literature to apply to that portion of the stress-strain curve which is in the vicinity of the elastic limit. It appears that a clear conception is not held concerning the underlying causes which affect this portion of the curve, and efforts directed toward increasing the terminology pertaining thereto seem to confuse rather than clarify the subject matter.

The importance which attaches to the accurate determination of the elastic limit, and the primitive state of the steel, depends somewhat on the uses to which it is to be put. In direct tension, service stresses range from a few thousand pounds up to (or exceeding) 150 000 lb. per sq. in. The latter stress is applied to steel in the form of hard-drawn wire. In most compression members the elastic limit practically fixes the maximum stress which the material will endure and maintain its shape without impairing the integrity of the structure of which the member forms a part.

For the purpose of enduring alternate stresses of tension and compression, the most satisfactory treatment of steel is one of some obscurity. Experience has demonstrated the desirability of limiting the bending loads in such cases to unit stresses of moderate degree. The problem of furnishing a steel of maximum durability for sustaining repeated alternate stresses has hardly been solved. The primitive properties of steel may be made to show decided increase in values by suitable regulation of its chemical composition, and also by heat and mechanical treatment. To establish whether these high, induced values are of permanent advantage is a matter which must be determined by exposure to different conditions of service, long continued.

There are certain situations in which complicated conditions exist. Steel rails are exposed to the direct bending stresses of train loads, which cause alternate stresses of tension and compression according to the position of the wheels with reference to given places on the rails, in addition to which there are internal strains at the top of the head and on the gauge side, due to the cold-rolling action of the wheels, and these strains augment cooling strains which are introduced in the rails in the process of manufacture.

The influence of primitive toughness in the metal and its advantages in steels when exposed to a large number of repeated alternate stresses of moderate degree is not apparent. Under such conditions all grades of steel may be ruptured without the display of appreciable elongation or contraction of area. Toughness of the metal is available for a time in resisting deforming loads, but its display is not witnessed in cases of repeated stresses, long continued. Some evidence exists which attaches importance to the tensile strength of the steel under these circumstances. Steels exposed to repeated alternate stresses at a blue heat have shown greater endurance than when tested cold. This in-

Mr. Howard.

crease in endurance takes place in the zone of temperature in which the tensile strength of the metal is much above that at atmospheric temperatures. In relation to this matter it should be remarked that the elastic limit is then somewhat lower than at ordinary temperatures of testing.

Slip bands in the micro-structure of steel have been pointed out as precursors to or attendant phenomena to rupture by repeated stresses. Microscopic examination has not in some cases furnished detectable changes in structure. In shafts which were ruptured by repeated stresses which strained the steel by amounts not exceeding one and one-third thousandths of an inch per inch, that is, up to 40 000 lb. per sq. in. fiber stress, rupture being reached after 150 000 000 repetitions, no observable change in structure was revealed. Still, it does not appear unlikely that manifestations of a macroscopic and microscopic order, witnessed in cases of pronounced deformation, may in kind be similar to those more minute changes which attend the rupture of steel under long-continued stresses of moderate degree. It would greatly aid in the matter of choosing the most suitable composition and treatment of steels if the phases through which rupture was reached were better known. It is a matter of no little regret that the research laboratories of America are not engaged in advance inquiry on these fundamental features which offer so much encouragement in their study.

In closing it may be remarked that Poisson's ratio, as found in tests conducted at the Watertown Arsenal, furnished a value for steel between one-third and one-fourth; to be more exact, the value appeared to be almost midway between these fractions.

Mr. Moore.

H. F. MOORE,* ESQ. (by letter).—This paper is an excellent discussion of the general action of iron and steel under stress, and should serve to place proper emphasis on the study of the physical behavior of the material in structures.

Mr. Prichard advocates the use of the term "elastic limit" to define the limit of proportionality of stress to strain. Some standard use for this term is highly desirable. At present "elastic limit" is used by some engineers to indicate the limit of proportionality of stress to strain, by other engineers to indicate the yield point of material, and by still others to indicate the stress at which permanent deformation of the material first appears. The last-named use of the term is recommended in the tentative standards of the American Society for Testing Materials, and is followed by most foreign writers. Some standard nomenclature is highly desirable, and though, for static conditions, the limit of proportionality could well be called the elastic limit, for conditions involving fatigue under repeated loads "permanent set" seems more significant than deviation from Hooke's law.

* Professor of Eng. Materials, Univ. of Illinois, Urbana, Ill.

Mr. Moore.

The writer believes that it is doubtful if the elasticity and proportionality of steel are perfect under any conditions, and would refer to the conclusions of Professor E. R. Hedrick, of the University of Missouri.*

Mr. Prichard quotes the test results of Hancock as a proof of the maximum shear theory for the failure of ductile materials. If the maximum shear theory holds for all conditions, the shearing strength of a material must be not greater than one-half the tensile or the compressive strength. Hancock's tests showed that, in general, the shearing strength of steel was greater than one-half the tensile strength, and the agreement of his "elliptical" formula with test results furnishes an empirical relation for various combinations of shearing stress with direct stress, rather than a confirmation of the maximum shear theory. Recent test results by Dr. Becker† indicate that for combined stress, in which the shearing stress is relatively low, the strain in steel is the determining factor for strength, and that, for steel, if the shearing stress is more than about 0.6 of the direct stress, the shearing stress governs. Dr. Becker shows that the results of Guest, Scoble, Hancock, and Mason, as well as those of his own tests, are in better accord with this dual law of strength than with any single law proposed for combined stress. Relative to this matter, the results of Matsumura and Hamabe‡ for cast iron are of interest. The results of their tests indicate that for cast iron the maximum strain theory holds.

The writer agrees with Mr. Prichard's conclusions as to fatigue of materials, but wishes to emphasize certain phases of fatigue phenomena. Attention is called to his statement: "There is nothing in experience or tests to cause fear of such a result [fatigue failure] when the material is of good quality and the stresses are not reversed". This is probably true for structural members for which the repetitions of stress number but a few million, but it would not necessarily be true for machine members in which the numbers of repetitions may number hundreds of millions.

The writer heartily agrees with the author's statement:

"Although experiments do not warrant the conclusion that steel and wrought iron can resist endless repetitions of stress to those limits [two-thirds of the statically determined elastic limit], neither do they warrant the conclusion that these metals cannot do so."

If experiments do not prove conclusively that materials can resist an infinite number of repetitions of stress, it would seem that safe

* "A Generalized Form of Hooke's Law", *Engineering News*, Vol. 74, p. 542, September 16th, 1915.

† Embodied in *Bulletin No. 85*, University of Illinois Engineering Experiment Station.

‡ *Memoirs* of the College of Engineering, Kyoto Imperial University, February, 1915.

Mr. Moore.

practice would dictate methods of computation for fatigue based on the supposition that destructive effects similar to those set up under high stress are set up with diminished intensity under low stress, and that it should be recognized that structures which could resist a few million repetitions of a given stress might fail under billions of repetitions of the same stress. This does not in any way call in question the author's statement:

"* * * both experiments and experience indicate that steel and wrought iron in bridges can resist to these limits for so long a period that the resistance may for practical purposes be considered permanent."

For the busiest steam railroad bridges, the number of repetitions in a normal "lifetime" for the bridge amounts to a million or two, and in most members the stress is not reversed. In other words, the criterion of static strength governs the design of bridges and buildings, rather than the criterion of fatigue strength. For machine members, and for structural members carrying reversed stress, the fatigue strength would be the governing factor in many cases.

Professor Basquin, of Northwestern University, has pointed out* that, for a considerable range of stress, the results of repeated stress tests of metals are well represented by an exponential equation:

$$S = \frac{C}{R^n}, \text{ or } \log. S = \log. C - n \log. R, \text{ in which}$$

S = fiber stress necessary to cause failure;
R = number of repetitions of stress necessary to cause failure; and
C and n are experimentally determined constants.

For the past year Mr. F. B. Seely, of the University of Illinois, and the writer have been engaged in an investigation of test data for repeated stress tests. Some tests have been made in the University of Illinois Materials Testing Laboratory, and data of other tests have been studied. As a result of this investigation the following modification of Basquin's formula is proposed:

$$S = \frac{B}{(1 - Q)\, N^{0.125}},$$

or $\log. S = \log. B - \log. (1 - Q) - 0.125 \log. N$, in which

S = fiber stress necessary to cause failure;
N = corresponding number of repetitions of stress (the "life" of the piece);
Q = ratio of minimum stress applied to maximum stress
($Q = 0$ for load varying from zero to a maximum,
$Q = -1.0$ for a completely reversed load);

* "The Exponential Law of Endurance Tests", *Proceedings*, Am. Soc. for Testing Materials, Vol. X, 1910, p. 625.

Mr. Moore.

B is an experimentally determined constant, approximate values of which are given in Table 5.

TABLE 5.

Material.	Value of B.
Structural steel and wrought iron	250 000
Steel, 0.45% carbon	350 000
Cold-rolled steel shafting	400 000
Tempered spring steel	600 000 to 800 000

It may be noted that these values are larger than those given by Mr. Seely and the writer in their paper before the 1915 meeting of the American Society for Testing Materials; the values in Table 5 are given as a revision of the earlier ones, and, in the opinion of Mr. Seely and the writer, are more reliable. An error in the method of deducing the value of B from test data has been corrected.

If the foregoing formula is applied to the determination of stresses in structural members for which the stress is not reversed (for structures, N is rarely more than 1 000 000 or 2 000 000 in the life of the structure), the value of S to cause fatigue failure, in practically all cases, will be found to be greater than the yield point strength of the material; hence static strength governs the design. This is in accord with the conclusions reached by Mr. Prichard. If, however, the stresses in machine members are investigated or those in oft-stressed structural members in which the stress is reversed, fatigue strength, in most cases, will be found to govern the design.

Different criteria of strength govern static strength and fatigue strength, respectively, and in the design of any structure or machine both static strength and fatigue strength should be considered.

Mr. Speller.

F. N. SPELLER, ESQ.* (by letter).—In reference to the last paragraph on page 1440, it is not often that the irregularities in elasticity of steel are referred to in papers of this kind. It is well known to most of those who are engaged in the physical testing of steel products that the true elastic limit of the metal is usually not developed on the first application of stress. A slight permanent set is generally found far below the true elastic limit. This seems to indicate that the stress on first loading is not always taken up equally by the grains and that there is, so to speak, some granular slack which must be taken in and the structure adjusted to the load until the stress is equally distributed in the section. The cause of this phenomenon is probably to be found in the irregular size and shape of the crystalline grains which constitute the normal structure of all metals. On the effect of straining of metals, Professor Sauveur makes the following suggestive statement†:

* Metallurgical Engr., National Tube Co., Pittsburgh, Pa.

† "The Metallography and Heat Treatment of Iron and Steel", 1916 ed., p. 93.

Mr. Speller.

"It is seen that, contrary to the general belief, the metals remain crystalline after the severest strain, and that the flow or plastic strain in metals is not a homogeneous shear such as occurs in the flow of viscous fluids, but is the result of a limited number of separate slips, the crystalline elements themselves undergoing no deformation."

The necessity for the adjustment of the structure of the metal by a preliminary stress applied below the elastic limit is recognized in some of the more modern specifications. For example, The Interstate Commerce Commission's "Shipping Container Specifications No. 3", for high-pressure cylinders, contains the following clause:

"Each finished and annealed cylinder must be subjected to a hydrostatic test of not less than 3 000 lb. per sq. in. in a water jacket, or other apparatus of suitable form, to furnish reliable data. The permanent volumetric expansion must not exceed 10% of the whole volumetric expansion at this pressure."

In "Specification No. 4" of the Interstate Commerce Commission (ammonia cylinders) a pressure of 800 lb. preceding the official test of 1 000 lb. is permitted. It would be better, in the writer's opinion, to make this preliminary test at a pressure more nearly approaching, but not exceeding, the official test.

The physical properties of steel are also temporarily altered by the mechanical machining of test pieces. It has become common practice to allow test pieces to "rest" for a day or two before pulling, in order to develop the true elongation and elastic limit. An increase of 2% elongation in 8 in. may be obtained after eliminating surface strains by this "rest cure", which is simply a form of slow annealing.

Mr. McCulloch.

J. A. McCULLOCH,* Esq. (by letter).—The writer has seldom had the privilege of discussing a paper which accords so nearly with his own conclusions.

At times he has been inclined to urge the restriction of the term "viscosity" to that measure of internal resistance which increases in direct ratio to the velocity of relative motion. It is a property of all fluids, by virtue of which they resist motion produced by shearing force, and, necessarily, it ceases with the cessation of motion; that is, viscosity offers no static resistance. For limpid liquids, something is known of the laws of this resistance to shearing motion. Little is known of its laws where substances offer also (at the same time) elastic resistance.

However, all know well that the restricted dimensional meaning of this term is violated in the ordinary measurements of the viscosity of water and the thicker liquids. Moreover, its present use, as describing the plastic flow of ductile metals, is justified by the best authorities, for Lord Kelvin says: "The term plasticity implies no more than does viscosity".

* McKeesport, Pa.

Mr. McCulloch.

The idea of a solid solution is difficult to comprehend, and does not at first appeal to our understanding, but the idea that many other substances are true fluids, even though they appear to be so solid as to be brittle to light blows, is equally difficult to grasp. Familiar examples are pitch and sealing wax. With elastic material, the case is even more difficult, because one finds it hard to conceive that the reversal of motion or lessening of stress changes the substance from liquid to solid. However, it is known that the conception of co-existing elastic and viscous actions has not led to experimentation which has yielded a satisfactory solution of the problem.* Difficulty in comprehending an idea is no refutation.

Misconception of the exhibition of elastic properties appears to be rather the rule than the exception. It may be due to false or partial education, or to the rush to train engineers in brief time, or to feeding "canned knowledge" in which no distinction is made between yield on primary loading and the recovery when the first load is released. For example, Pender gives:† "Ability to return to its original form after deformation is called elasticity"; and Kent states‡ that within the elastic limit, "* * * for such materials [iron and steel] the modulus [of elasticity] is practically constant * * ." Again, Kent§ quotes the late J. B. Johnson, M. Am. Soc. C. E., as follows: "The modulus of elasticity is the most constant * * * property of all engineering materials." The treatment of the subject is too brief, and is generally inadequate. Any one having accepted such ideas receives a shock when he turns to Kirkaldy's "Report L", or the reports on "Tests of Metals" at Watertown, and notes that the sets for iron and steel eye-bars run roughly from 2 to 17% of the elongation under the stresses applied before the elastic limit is reached. Fig. 7 illustrates the average percentage of sets on first loading of a few specimens of steel and wrought iron.

It may be that this dereliction of the elastic properties can be eliminated by a single loading to a slightly greater stress than that at which the sets were measured. Some tests|| which the writer has had to look after seem to indicate that several repetitions of stress are required; but, for steel, it is certain that the elastic properties are rendered nearly perfect by application of stress, and that this can be carried up to and beyond the elastic limit or yield point exhibited

* One of the most difficult features of the visco-elastic properties of steel is exhibited by the sudden tensile test which causes greater elongation than when similar material is pulled slowly. Indeed, Trouton and Rankine (*Philosophical Magazine*, Vol. 224, 1904, p. 536, etc.), speaking of their experiments on viscous traction, conclude that "the explanation of the phenomena must be sought for on altogether different lines from those based on mixed viscous and elastic action in the way commonly attempted."

† "American Handbook for Electrical Engineers," p. 1418.

‡ "Mechanical Engineers' Pocket-Book," p. 351.

§ *Ibid*, p. 352.

|| Not published.

Mr. McCulloch.

on primary loading. Under certain conditions, this perfecting of the elastic properties by application of high stress may enhance the utilitarian available strength remarkably.

Returning to the experiments that showed the necessity for more than one application of stress, it may be said that the measures were commercial testing, and had to be made with dispatch, so that what is known as "Webber-effect" or *Nachwirkung* may have complicated the observations. Indeed, some few slowly conducted tests clearly indicated this "afterworking" of elastic recovery.

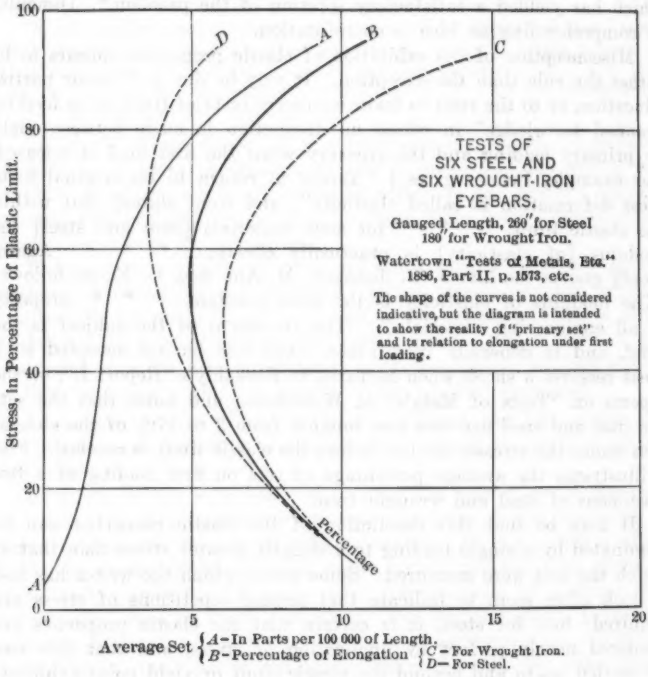

FIG. 7.

It would be wrong to dwell on this set on primary or first loading were it not for the fact that it is a common mistake, and ignorant men entrusted with the framing of specifications for steel frequently err by inserting a requirement that on removal of the first load no evidence thereof shall remain in the form of permanent set. In his early experience the writer was told to draw up a specification for coiled (helical) steel springs. It was promptly rejected by all makers

because of a requirement that there should be no set on first loading. For more than twenty years this erroneous idea of "no set on first application of load" has been specified, and the writer has become convinced that the proper and true idea of "primary set" has not been given the credence that is warranted by the ready accessibility of its proof. This type of set is non-indicative of quality. Philip Schidrowity, writing on "Rubber", says that even there it is not indicative, but that the rate of decrease in the area of the hysteresis loop on successive loadings does connote quality. Dr. Steinmetz has called attention to this "physical hysteresis" and its analogy to the electro-magnetic phenomenon of the same name.* Mr. McCulloch.

Under nearly every condition of the application of steel to its service, this set on first loading ("primary set") is wholly negligible. However, in the case of columns, the writer would attribute much of their notable dereliction on first loading to this primary set in conjunction with the variability of the elastic modulus where that property is measured by either yield or recovery from step to step of first loading, as shown by many of the Watertown tests.

One often hears expression of the erroneous idea that straining steel is injurious, but stress which does not over-strain puts steel in "a state of ease" where it acts as though it were nearly perfectly elastic. Even over-straining steel (if not carried to a ruinous extent), when allowed a reasonable time to recuperate before the next application of high (but lower) stress, will exhibit the characteristics of the "state of ease". The set will not be increased to more than that produced by the earlier strain; that is, repetitive loadings do not cause additional or cumulative distortion in steel. In this, steel is wholly unlike some of the soft metals, and, therefore, is vastly superior to them as a structural material.

The notable and great enhancement of the physical properties of steel by strain are well known, although many attempts have been made to ascribe the benefit to some more recondite phenomenon. Forging, rolling, drawing, etc., all improve steel, if the pressure is applied in a manner that causes a general flow; that is, when the pressure is not applied in a manner that causes high local stress.† When high local shears are caused, the general quality may be injured, but, by skillful application of this principle, Herr Mannesmann

* *Engineering News*, December 5th, 1912, p. 1051.

† Caution is required. The homogeneity of steel is not "perfect", but the imperfections (some visible under the microscope) are so small when compared with those of wrought iron, that there is some propriety in the use of the term "homogeneity". The imperfections of the two materials are so dissimilar that they belong to different orders of magnitude (to use mathematical language). Even the slag enclosures of wrought iron do not preclude benefit from stress. Dr. A. Leon, writing on "Irregular Strains Due to Non-Homogeneity of Materials" (Int. Assoc. for Testing Materials, No. 9, VIII, 1909), indicates that, although the material adjacent to cavities and enclosures may be at stresses vastly higher than the average applied stress, this localizing of stress largely disappears when ductile metals are strained beyond the yield point.

Mr. McCulloch. turned the failure of his planishing mill into the notable advance that bears his name as a method of producing hollow blooms which are of very high quality. Wire which has been drawn has been subjected to great traction at the same time that great external pressure was applied by the die. The stresses are far above the yield point, and the quality of the material is enhanced to a measure greater than the elimination that annealing involves when putting in shape for suspension bridges. Although what is spoken of as heat treatment is doubtless mostly due to rapid cooling through the critical range, it has long been the writer's idea that the rapid cooling of the surface induces a great pressure on the interior, thus producing a benefit from stress, perhaps analogous to, but less profound than, fluid compression.

This fact of paramount importance remains, that steel is improved by strain. When the stress exceeds the yield point and is released for a sufficient time, the enhancement of the quality of the steel is immediately available and of great practical value, regardless of whether the stress is applied by the maker or user. High straining, if done in an ignorant fashion, may injure steel or other materials.

Mr. Jonson. ERNST F. JONSON,* ASSOC. M. AM. SOC. C. E.—There are two points in this paper on which the speaker wishes to comment.

The author seems to conceive of the flow which takes place in ductile metals when stressed beyond the yield point as if it were due to a change in the metal from the solid to the liquid state. The energy required to bring about this change of state he seems to regard as a part of the work done by the load. This, however, is not in accordance with the facts. All the work done by the load previous to the beginning of flow is stored in the test piece as elastic energy, and, therefore, is not utilized in changing the state of the metal, as is the heat which is transformed into fluidity energy when a solid melts. One of the main distinctions between a solid and a liquid is the difference in their elastic limits. The elastic limit of the solid has a certain positive value, but that of a liquid is zero. As the temperature rises, the elastic limit diminishes until it becomes zero at the melting point. Flow takes place in solids, as well as in liquids, only when the shear exceeds the elastic limit; liquids flow under an infinitesimal shear because the elastic limit is zero; solids flow only when the shear is infinitesimally in excess of the elastic limit of the material.

The author's use of the words "sliding" and "slipping" in connection with flow seems to be unfortunate, because flow is something entirely different from slipping. Flow consists of an indefinitely extended, angular deformation, which is the resultant of a diagonal tension and a diagonal compression perpendicular to it. As soon as slipping takes place the specimen breaks and the flow stops. The fundamental differ-

* New York City.

ence between slipping and flow is best realized by remembering that the former is resisted by friction, and that the resistance produced by the latter is viscosity, two entirely different phenomena, following different laws; friction is a function of the pressure, and viscosity is independent of pressure and is a function of velocity and temperature. Mr. Jonson.

Metals are not uniform in elastic limit in all their parts, and therefore they do not flow uniformly. The flow naturally begins in the particles of the lowest elastic limit; but, owing to the fact that flow raises the elastic limit, the flow soon spreads to the particles of higher elastic limit. As the flow thus spreads throughout the mass of the metal, its quantity increases, and therefore the product of the elastic limit and the cross-sectional area increases at a decreasing rate until it ceases to increase and begins to decrease. The point at which this change takes place is the ultimate strength. When the elastic limit becomes equal to the cohesion of the material, no further stretching is possible and rupture occurs.

The author seems to be under the impression that shear is a peculiar kind of stress, an elemental stress, but shear is rather the resultant of two or three linear stresses acting at right angles to each other. A simple or two-dimension shear arises when two principal stresses of opposite kind but of the same magnitude act in the same point. A compound or three-dimension shear arises when two principal stresses of the same kind and magnitude, and a third principal stress of the opposite kind and twice the magnitude or greater, act in one point. Flow begins when the shear reaches the elastic limit, but rupture is not produced by shear. Tensile stress alone produces rupture, for rupture cannot be produced by compressive stress. The only condition under which pure compressive stress is possible is that of a specimen immersed in a liquid under hydrostatic pressure, and experiments have shown that rupture is not produced in this way. Hence, it follows that rupture is due to the tensile components. Since tensile or compressive stress may exist without shear, but no shear can exist without both tensile and compressive stress, it is evident that shear is not a simple form of stress.

T. E. Stanton,* Esq. (by letter).—The writer has read this paper with great interest, and considers it a valuable contribution to the literature on the strength of materials. There are one or two statements, however, to which he would like to call attention because he thinks that recent researches have shown that they need some modification. On page 1431, it is stated that in pieces subjected to alternate direct tension and compression, an increase in the rapidity of the alternations reduces the safe range of stress. Again, on page 1456, referring Mr. Stanton.

* Teddington, Middlesex, England.

Mr. Stanton. to the National Physical Laboratory tests on alternations of direct stress (Table 4), the author states:

"In structural members, however, as the frequency of the alternations is much less than in these tests, and as periods of rest are interspersed between alternations, it is fair to assume that the limits between which the stresses can alternate are greater than in the tests."

These conclusions are apparently based on Reynolds and Smith's experiments,* in which a very large reduction in the safe range of stress was observed as the rate of alternation increases from 1 400 to 2 500 per min. The writer believes that it is now coming to be recognized that these results were peculiar to the testing machine used. At any rate, in the modified Wöhler method of test, which has been used extensively at the National Physical Laboratory during the last 10 years, no trace of a speed effect on the safe range of stress has been found below 2 and 2 200 alternations per minute. Further, periods of rest between series of alternations do not appear to have an appreciable effect on the total number of alternations for fracture. Again, in discussing the question of fatigue, on page 1433, Mr. Prichard states:

"* * * the greatest strength of steel or wrought iron under repeated stresses is beyond, and in some cases far beyond, the yield point."

Assuming that by the term "repeated stresses" is meant stresses varying from zero to an upper limit, the statement needs modification, as in many steels the maximum safe stress for repeated loadings from zero is well below the yield point. For example, in Mr. Bairstow's valuable paper† on the range of the elastic limits, with which Mr. Prichard does not seem to be familiar, experiments on an axle steel with a yield point of 24.9 tons per sq. in. showed that in repeated loadings from 0 to 23.2 tons per sq. in. no sign of want of elasticity occurred until after 6 000 loadings, when a permanent extension of the order of the yield took place.

The writer thinks it is not sufficiently recognized by engineers that the phenomenon of repeated loadings of a structure from zero to an upper limit is only a particular case of cyclical variations of stress in which the lower limit of stress is zero, and that it has been proved conclusively that the safe range of stress under such conditions is appreciably less than in the case of reversals of stress between equal values of tension and compression.

Mr. Howe. HENRY M. HOWE,‡ ESQ. (by letter).—The Society is to be congratulated on this very clear and interesting exposition of the current theory of plastic deformation, and on the reasonableness of the inferences drawn from our present very fragmentary knowledge. This

* *Phil. Trans.*, Royal Society, Vol. 199, p. 265.

† *Phil. Trans.*, Royal Society, Vol. 210, p. 35.

‡ Bedford Hills, N. Y.

Mr. Howe.

theory, of course, lacks full confirmation, failing, for instance, to explain why, after a heating so gentle as to intensify the hardness caused by the deformation, no traces of the amorphous metal along the slip planes can be detected, though, according to this theory, it ought to be prominent.* In particular, one welcomes the assertion on page 1459 that the real factor of safety in such cases must be based on the elastic limit and not on the tensile strength. This, of course, refers to what one may call "hypo-elastic" uses, as in structures which, in the nature of the case, must not be subjected to stresses great enough to cause important plastic deformation. That this is true of bridges and buildings is evident. For what may be called "hyper-elastic" uses, the tensile strength may possibly be a more useful measure of fitness. A hoisting cable, for instance, need not be unfitted for its use by a degree of permanent stretch which will raise its elastic limit very greatly.

Perhaps our view of the whole subject may be clarified by looking at the hyper-elastic part of a tensile stress strain diagram as approximately the locus of the elastic limit. If, at any moment after the yield point has been passed, the stress is released and re-applied, no new permanent set arises until the new stress reaches approximately the maximum hitherto applied, which means that the stress at that point in the diagram is approximately the existing elastic limit of the test piece. The first sentence of this present paragraph is only a generalization from this particular case. In this view, the tensile strength is the maximum elastic limit which the material is capable of developing under other roughly similar conditions, as when a cable is slowly strained beyond its primitive elastic limit up to the point at which it finally breaks.

In this view, the drop of the diagram at the yield point and its later rise represent the algebraic sum of (*A*) the weakening which the test piece is undergoing, (1) because of its progressive loss of section, and (2) from the mobilizing of part of the metal, initially all crystalline; and (*B*) the strengthening which each unit of section is given by the solidification of the momentarily mobilized metal, or, in short, by the plastic deformation itself. At the beginning of the yield, the curve may drop sharply because now the section is decreasing rapidly and mobilization is rapid, whereas the strengthening, which will soon follow this mobilization, has not yet reached considerable proportions. The flat part or jog means that here the strengthening of the material by the deformation is just equalling the loss of strength represented by the simultaneous mobilization of crystalline metal plus the loss of section. This part is probably never truly flat, but a series of waves. The rise of the curve, like the up side of each of these waves, means that now the strengthening caused by the deformation is ex-

* "Metallography of Steel and Cast Iron", pp. 526, 625, 626, 634, and 682.

Mr. Howe.

ceeding the weakening due to the loss of section, and the final drop on passing the so-called tensile strength or maximum load, like the down side of each of the waves in the jog, means the reverse. In this view the rise of the diagram beyond the jog changes from a miracle to an almost prophesiable phenomenon. On this view, why should hypo-elastic service stresses be based on the so-called tensile strength, which is only a certain strength capable of being developed under conditions wholly different from those of service, and wholly unapproachable in service, instead of on the elastic limit, which is the only strength existing in that service?

The writer had hoped that Mr. Prichard, in addition to showing the practical ineffectiveness, for hypo-elastic services, of the elevation of the elastic limit, or, more briefly, the strengthening, by service deformation itself, would have touched on the important question of the effectiveness of such elevation by pro-service deformation, such as cold-rolling and cold-drawing. One of the important questions before us is as to the limits within which the strengthening caused by pro-service deformation is effective. There is much to suggest that, under indefinitely repeated reversals of stress-sign, any such pro-service strengthening is wholly ineffective, and that it is the primitive elastic limit alone that determines the endurance, that is, the fatigue strength. Indeed, there are well-informed and just writers who imply that this ineffectiveness is established and certain. If this is true, then the measure of strength of axles, shafting, etc., is given, not by the elastic limit as observed in the material as delivered, but by that determined after the removal of all pro-service elevation of the elastic limit by plastic deformation, and hence the reception tests should be made on pieces annealed say at 600° cent. for the purpose of removing the strengthening caused by cold- or cool-rolling, or any other form of plastic deformation. The question whether this pro-service strengthening is effective or fictitious under indefinite reversals of stress-sign is of an importance which calls for decisive tests. If ineffective under indefinitely repeated reversals, then the question comes up, for bridge engineers and the like: "What are the limits within which this pro-service strengthening is effective, and beyond which it ought to be effaced before making the reception tests, by 600° annealing or its equivalent?"

There are a few minor points which may merit attention. Two reasons suggest themselves for considering the use of the term "proportional limit" rather than "elastic limit" for the limit determined directly from the stress-sign diagram. First, "elastic limit" has been used so widely and persistently in the sense of "yield point" that its use may still leave the reader in doubt as to which is meant, whereas there is no such doubt about "proportional limit". Second, that which we know to be the elastic limit is the maximum stress which just fails

to cause a permanent set. It is true that every refinement of measurement lowers the elastic limit which we observe by releasing the load and remeasuring the measured length. Hence the ideal elastic limit is that observed with perfect instruments, and hence it can never be actually determined, but only approximated. Nevertheless, its determination is essentially different from that of the proportional limit, which, for like reasons, can only be approximated. If it is true that the proportional limit and the elastic limit coincide—and, however probable this may be, it is not yet known to be a universal law—then it is a purely empirical observation. Might it not be well to use these terms "elastic limit" and "proportional limit" each as indicating the way in which the determination is made? There are those who actually determine the elastic limit by release and remeasurement, and prefer this procedure. Is it not a little arbitrary to deprive the term "elastic limit" of its natural and obvious application to such determinations, and apply it by force to the proportional limit? What is the gain to offset these disadvantages? Mr. Howe.

Even if rupture through fatigue is always preceded by tearing, does it follow, as suggested on page 1432, that fatigue is always accompanied by tears? Why may not a very important degree of true fatigue occur before even sub-microscopic tears form?

What is gained by complicating the notion of slip by introducing rotation, as on page 1437? The conception of Ewing and Rosenhain, as well as that of Beilby and other writers, if the writer understands them aright, is that slip itself is purely vectorial, consisting of translation absolutely without rotation, though it may be accompanied by rotation which in itself leads to a radically distinct mechanism of deformation, *viz.*, twinning.

Later results have thrown very serious doubt on the inference drawn from Howard's experiment (page 1445) that hydraulic pressure does not affect the properties of metals.

Is the conception (page 1450) that during continued flow there is a prolongation of the mobile state of certain individual particles, as easy and probable as the alternative conception that, during such flow, each particle passes with relative rapidity from the crystalline through the mobile to the rigid amorphous state, and that the continuousness of the flow represents the succession of various sets of particles in this progress?

On either view flow is replaced by rupture as soon as the supply of residual crystalline metal is so far depleted that it no longer suffices to generate, under continuing deformation, mobile metal fast enough to heal the cracks which that same deformation is causing in the metal which has passed beyond the mobile into the rigid amorphous state. The conception that the mobile metal is prevented by continued deformation from setting would imply that such continuance would

Mr. Howe. defer greatly this time of depletion, or, in other words, increase the ductility very greatly, which is not true.

Mr. Irwin. A. C. IRWIN,* ESQ. (by letter).—The author is to be congratulated on having produced a paper of exceptional merit. It should be of great interest to engineers as an enlightened exposition of a convenient theory and a clear statement of certain changes in the properties of wrought iron and structural steel produced by strain. It is hoped that it will stimulate engineers to a more active interest in the influence of the proximate constituents on the physical properties of iron and steel.

It is hoped also that the use of formulas for fatigue in the design of ordinary static structures will be finally discarded, as the theory advanced in this paper, as well as other theories well authenticated by experiments, show that in ordinary static structures, where no reversal of stress occurs, "fatigue" either does not exist, or is of no consequence.

The theory proposed by Mr. Prichard is open to some logical objections, as well as being apparently at variance with certain knowledge obtained and well-proven by various investigators. According to this theory, the internal structure of iron and steel is made up of "grains", "particles", or "crystals"—using these terms interchangeably—and an intergranular material which exists as a film on the surface of each grain, and fills the intergranular spaces. The "grains", "particles", or "crystals" possess and retain the property of almost perfect elasticity under either elastic or non-elastic deformation of the piece. The film, or intergranular material, however, becomes a viscous liquid when the piece is strained beyond the elastic limit, but re-solidifies with great rapidity on the release of the straining forces. The groundwork of Mr. Prichard's theory may be found in the first paragraphs on pages 1430 and 1432, and the second paragraph of page 1450, from which the following conclusions may be drawn:

First.—Elastic deformation is effected wholly by deformation of the "grains", "particles", or "crystals".

Second.—Non-elastic deformation or permanent set is effected wholly through plastic flow of the intergranular material, which causes the grains to slide over each other into new positions—the grains themselves undergoing only elastic deformation and regaining in time their original dimensions, shapes, and bulks, on the cessation of the external straining forces.

Third.—Failure of an over-strained piece takes place wholly by failure of the intergranular material, the grains themselves retaining their integrity and their nearly perfect elasticity.

Fourth.—The recovery of a piece from over-strain is dependent on the extent of elastic deformation of the grains. The push or pull

* Chicago, Ill.

exerted by the forces of elastic return of the elastically strained grains on the "viscous liquid" is all that prevents its immediate re-solidification on the release of the external straining forces, and the magnitude of these forces of elastic return is sufficient to prevent complete re-solidification for a considerable time. Mr. Irwin.

It seems that, if the last conclusion is true, the following should also be true, *viz.*, that elastic change of form of the grains of a piece, under the action of external straining forces, exerts a push or pull on the intergranular material of such magnitude as alone to cause a degree of liquefaction; and that, as the grains suffer considerable elastic deformation at stresses near to, but below, the elastic limit of the piece, a certain amount of liquefaction of the intergranular material must occur, even in elastic strain, to accommodate the changed dimensions and forms of the grains. Some period of time would then be required for recovery from elastic strain, just as in non-elastic strain, because, in both cases, there is the retarding effect of the forces of elastic return of the elastically strained grains; and, furthermore, it would be expected that the time for recovery from elastic strain would be some considerable portion of the time for recovery from non-elastic strain, the difference in the two cases being merely one of degree in the magnitude of the same kind of strain. The time required for recovery from any considerable over-strain may be hours or days, and we would be led to expect that the time for recovery from elastic strains produced by stresses at nearly the elastic limit would be at least quite appreciable. On the contrary, no appreciable time is required for recovery from elastic strain, and, therefore, we conclude that no liquefaction or flow of intergranular metal takes place. Further, as liquefaction and retardation of solidification are but counterparts of each other effected by exactly the same kind of forces, *viz.*, those of elastic strain and return, and as no time is required for solidification because of these forces under elastic strain, we conclude that no such liquefaction as that described by the author takes place under non-elastic strain.

The second and third conclusions derived from Mr. Prichard's paper, *viz.*, that non-elastic deformation and final failure are respectively dependent wholly on the plastic flow and failure of the intergranular material, and, accordingly, that the grains themselves retain their integrity and nearly perfect elasticity, are at variance with views—held by metallographers—which have been well proven by experiments.

"Under a progressively augmented strain, rupture takes place, not at the crystal boundaries, but through the crystals themselves."*

* "The Crystallization of Iron and Steel", by J. W. Mellor, p. 91.

Mr. Irwin.

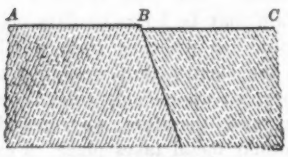
"Fractures in fact are always trans-crystalline in properly treated steel, an intergranular fracture being clearly pathological, as for instance, in burnt steel."*

"The plastic deformation of all kinds of iron is primarily in their ferrite. The cementite present, whether pearlitic or proeutectoid, may break or bend, but it probably does not yield plastically to any large degree."†

"The manner in which a metal yields when the strain exceeds the elastic limit is by slips which occur in the cleavage or 'gliding' planes of the individual crystals."‡

The micro-structure of wrought iron and steel is essentially crystalline. In wrought iron and low-carbon steel, this crystalline structure is most perfect in the free ferrite crystals which exist in predominant quantity. Free ferrite crystals are true crystals, in that they are composed of an enormous number of crystalline elements, molecules, or "brickbats", arranged in perfectly regular tactical order.

These elementary molecules or "brickbats" composing a crystal grain have their like axes and faces all parallel in any given crystal. The axes of the "molecular brickbats" in adjoining crystals, however, are not usually parallel, so that each crystal has its own individual orientation.§



(Before Plastic Strain)

Trans.* of the Royal Soc., 1900; "The Microscopic Analysis of Metals", by F. Osmond, 1913; W. Rosenhain, *Journal*, Iron and Steel Inst., 1914, No. II, p. 367; and "Introduction to Physical Metallurgy", by W. Rosenhain, 1915.

§ A popular and lucid explanation of crystallization in a pure metal and the effects of straining Swedish iron, together with an electrical theory of plastic strain and fatigue, is given by James Alfred Ewing in *Memoirs and Proceedings*, Manchester Literary and Philosophical Soc., Vol. 51, 1906.

between groups of tactically arranged molecular "brickbats". In Fig. 9, at *a*, *b*, *c*, *e*, *f*, and *g*, are steps in the polished surfaces of the crystals after plastic strain of the piece. These steps are produced by the slip of the molecules on one side of a glide plane over those on the other side of it. The dark lines shown by these breaks in the polished surface of each crystal, under the microscope, have been called "slip bands" and are the "slips" to which the author refers on page 1437. As previously noted, these "slips" are intra-crystalline and not inter-crystalline, as we are led to believe from the paper. Mr. Irwin.

Of so-called impurities that always occur in commercial iron, *viz.*, carbon, silicon, phosphorus, manganese, and sulphur, silicon and phosphorus are retained by the iron in solid solution, and carbon, manganese, and sulphur form compounds with the iron (ferrite) and with themselves, which compounds are rejected to the crystal boundaries or along crystallographic planes while the metal is passing through the critical range; that is, during conversion to the final crystalline structure of ordinary temperatures.

The rejected impurities are in the form of definite compounds with iron; the carbon as carbide of iron (Fe_3C, or cementite), the manganese as manganese sulphide (Mn S) and manganese carbide (Mn_3C). The cementite combines with ferrite to form pearlite, which appears as a lamellar structure of very thin alternating plates of cementite and ferrite. The ferrite not required to form pearlite is known as "free ferrite", and crystallizes generally in the cubic system.

Steel having less than about 0.85% of carbon is known as hypo-eutectoid, and is composed essentially of pearlite and free ferrite. These constituents vary proportionally with the carbon present. Thus, pure iron is made up of ferrite crystals with no pearlite present. With a very slight carbon content, the ferrite crystals will have interspersed between them small pearlite masses. With increase in carbon, the pearlite increases in proportion until a connected net is formed, the meshes of which are completely filled up with ferrite crystals. With further increase in carbon, the pearlite net occupies more and more space until it becomes the meshes of a ferrite net, and finally the steel is composed entirely of pearlite. Steel composed entirely of pearlite is known as eutectoid steel, and results when the carbon content is just sufficient to form cementite in such quantity as to require just the total ferrite present to form pearlite. The carbon content of eutectoid steel is variously given as from about 0.82 to 1 per cent. If the cementite is in excess of the quantity required to form pearlite, the resulting steel is known as hyper-eutectoid. In the latter case excess cementite is known as "free cementite".

The physical properties of ferrite, pearlite and cementite, according to Sauveur, are as given in Table 6.

Mr. Irwin.

TABLE 6.—PHYSICAL PROPERTIES OF FERRITE, PEARLITE, AND CEMENTITE.

Constituents.	Tensile strength, in pounds per square inch.	Elongation, percentage in 2 in.	Hardness.
Ferrite	50 000	40	Soft.
Pearlite	125 000	10	Hard.
Cementite	5 000 (?) *	0+	Very hard.

* It seems very probable that cementite has a considerably higher tensile strength than 5 000 lb. per sq. in., and an appreciable elongation percentage.

In Table 7 is reproduced the author's Table 1, except that computed percentages of ferrite, pearlite, and cementite are substituted for the columns for yield point. It will be noted in this table that the elastic limit increases, in general, with the percentage of pearlite, and indicates clearly the influence of this constituent on the elasticity of the material. It is well known, too, that the total percentage of elongation at ultimate decreases, in general, with increase in the carbon content, that is, with the increase in the percentage of pearlite. This is to be expected from the comparatively low elongation of pearlite given in Table 6. Moreover, the percentage elongation given for pearlite is much less than that obtained from low-carbon or "medium" steels. It is evident, therefore, that, although the intergranular material, that is, pearlite, greatly influences the elastic strength, it is not responsible for the ultimate elongation of such steels, and that we must credit the ferrite with by far the most important role in plastic deformation.

* Free cementite.

When wrought iron, or low-carbon or "medium" steel, is strained within its elastic limit, the pearlite takes stress in proportion to its strength to resist elastic deformation, and lends aid to the weaker ferrite crystals. So long as the elastic limit of the pearlite is not passed, there is no slip in the ferrite grains, excepting, perhaps, in isolated grains, the orientation and disposition of which, with respect to the surrounding pearlite and adjacent ferrite grains, presents them in the most unfavorable position to resist the straining forces. When the elastic limit is passed, small slips or cracks occur between or through the plates of the lamellar pearlite, or at the boundaries between ferrite and pearlite, or at any of these places in combination, so that a greater proportion of stress is thrown on the ferrite. Moreover, the support accorded to the ferrite by the pearlite is thus removed, to a degree, and the result is slip along the crystallographic planes of the ferrite crystals. This slip is accomplished by the disarrangement of molecules along the glide planes affected—the greater the slip the greater the disarrangement and the more molecules affected. Disarranged molecules appear as an amorphous material in the planes of slip, and, under severe over-strain or many reversals, at the intersection of the slip planes with the boundaries of the crystal grains. This amorphous material forms a very thin film—of perhaps molecular thinness—along the slip planes, and when extruded at the grain boundaries may fill cracks in the intergranular material that register with the planes of slip. If the over-strain is slight, the disarranged molecules will rearrange themselves, in something like their former orientation, with those of the crystals from which they were broken; but, in the case of considerable over-strain, their disarrangement is so great that they remain in an amorphous condition. This amorphous metal is hard and quite strong, and binds the parts of the crystal so strongly together at the planes where slip occurred that the planes on which no slip has occurred are planes of weakness in comparison. Thus, the weak portions of the piece have their strength increased and a greater application of stress will be required to produce further plastic deformation than was required in the first instance—the deformation being now effected by slip along planes not thus far affected. This process results in the development or increase in the elastic strength of the piece as a whole. Mr. Irwin.

Under severe over-strain, slips occur, not only along the three principal glide planes of the crystal, but along other planes, so that the polished surface of the crystal becomes checkered with numerous intersecting slip lines. Final fracture of the piece is initiated by the opening up of a minute crack along a slip plane of some crystal which registers with a minute crack or slip in the pearlite. The crack quickly widens and propagates to other crystals through the more or less broken up pearlite, until fracture takes place. If the

Mr. Irwin.

stresses producing final failure are applied quickly, as by shock or by continuous rapid reversals, "the resulting fracture exhibits the crystal faces upon which slip has taken place as a number of bright facets resembling those produced in a 'brittle' shock fracture, and it is this appearance which has led to the mistaken idea that alternative stresses cause metal to become crystalline."*

The time of recovery from over-strain will depend on the degree of disarrangement of the molecules and the hindrance to their adoption of the most stable arrangement possible under their condition of confinement.

The process of failure by "fatigue" under repeated reversals of stress is explained on the same basis of slip in the crystalline grains. The amount of slip, and hence formation of amorphous metal, is greatly augmented by reversal of the direction of slip before the disarranged molecules can adapt themselves to the new conditions, that is, before the amorphous metal can harden. The slips in the weak crystal are thus continued until a crack is developed which spreads to other crystals. Fracture finally occurs at a unit stress for the piece much below that required for a stress in one direction intermittently applied. In the latter case, the primitive elastic limit arising from slight slips in unfavorably oriented and located crystals is eliminated, and the normal elastic limit developed in the piece. Therefore, the use of fatigue formulas in proportioning the members of static structures under uni-directional stress has no rational basis. Moreover, their use produces a poorly balanced design. If fatigue formulas are recommended for the reason that they allow a margin for impact, the reply is that such use of them relegates to the realm of unscientific guessing a matter about which fairly definite knowledge is available in the various reports of the Sub-Committee on Impact and Secondary Stresses of the American Railway Engineering Association.

In addition to making the provision for dead load relatively too small for long-span bridges, "fatigue" formulas (and others) result in making the provision for live load in certain members relatively too small in short- and medium-span bridges. This becomes apparent when it is desired to load the bridges to their maximum carrying capacity.

In general, the writer believes that a properly balanced proportioning of bridge members is most likely to result from separate consideration of all stress-producing factors and the use of the highest unit stress to which the material may safely be subjected. The assumed loading should then be the heaviest that will ever come on the structure, and the total stress that obtained by taking the sum of dead load, live load, live-load impact, and the secondary stress

* "An Introduction to the Study of Physical Metallurgy", by W. Rosenhain, p. 254.

resulting from the deformation produced by the primary stresses. With this method of design, it will not be necessary to replace bridges because of certain weak members before they are loaded to the maximum carrying capacity of the majority of their parts. Mr. Irwin.

DAVID A. MOLITOR,* M. AM. SOC. C. E. (by letter).—The author, in this paper, brings to the attention of the Profession a valuable collection of data which should serve to strengthen similar arguments and opinions previously advanced by others. Mr. Molitor.

It should also materially assist in relegating to the past, several formulas which have retained a place in specifications for no better reason than a lack of moral courage to cast them out.

One very important matter, also clearly indicated by column tests other than those given in the paper, is the remarkably close agreement between the ultimate strength and elastic limit, or better, limit of proportionality. Of course, this can only be true for columns of considerable length; for very short columns or cubes, the ultimate strength is practically the same in both tension and compression and, for columns still shorter than the side of a cube, the ultimate compression may be called the flowing strength, and is the highest strength attainable. These three classes of failure under compressive stress are explained by combined bending and direct stress for long columns, true direct stress for cubes, and flowing stress for plates.

In tension specimens we observe an elastic limit approximately the same as for compressive stress, though the ultimate strength is about twice as great.

We are naturally forced to the admission that any stress in excess of the elastic limit, whether it is tensile or compressive, will result in some permanent injury to a structure, owing to a permanent deformation due to the excess stress. This may not be true of a piece not forming part of any structure, but we are usually concerned with structures consisting of a multiplicity of pieces in which each piece has a certain duty to perform. Hence, a sufficiently great number of repetitions of stress in excess of the elastic limit must ultimately cause failure, a fact clearly demonstrated by the experiments of Wöhler, Bauschinger, and others.

Therefore, in so far as we are concerned with structures, the elastic limit of the material, both in tension and compression, must also be the limit of permanent usefulness of any given structure, even though the ultimate strength in tension for a single condition of stress, may be double that in compression for any of the component parts.

In the case of the collapse of any bridge, as a result of gradually applied overload to the point of failure, the initial failure will always be in the highest stressed column and not in a tension member, pro-

* Detroit, Mich.

Mr. Molitor.

vided the design was based on a uniform factor of safety with respect to the elastic limit of the material used. To avoid this, columns would have to be made almost twice as strong as common practice demands. The Quebec Bridge failure clearly points to this conclusion.

However, a structure designed for unit stresses approaching the elastic limit simultaneously in all its members for a 100% overload, would obviously have a factor of safety of 2 throughout, would be uniformly safe, and would be considered a prudent design. Unfortunately, most bridges have not been designed in this way in the past, and generally have some members in which the unit stress resulting from overload increases at a greater rate than the rate of increase in the load applied. All members, in which the dead-load stress is of opposite sign to that of the maximum live-load stress, belong to this class; likewise all members, the live-load stresses of which are produced by a partial loading of the span.

Various specifications have been written to obviate this difficulty, but, in most cases, these involve the addition of metal to certain members, without any logical system.

The writer has devised a method of design which effectually overcomes the difficulties here mentioned, with the idea of producing structures of uniform strength throughout, for an overload of 100% in the live load, without ever exceeding the elastic limit of the material. As a basis of design, the allowable unit stress in tension is taken as $f = 16\,000$ lb. per sq. in., and, in compression, $f = 16\,000 - 60\,\frac{l}{r}$ for fixed ends, and $f = 16\,000 - 80\,\frac{l}{r}$ for one or two hinged ends. This method is described here for the first time.

The stresses in the chord members and end posts are directly proportional to the total loads covering the entire span length, hence to double the live load will increase the unit stresses in these members by a constant percentage, always less than 100% so long as the dead-load stress is greater than zero. However, this same overload will generally increase the unit stresses in the web members in a much greater ratio than for the chords, hence the following specifications:

Members subjected to dead- and live-load stresses of the same character, and in which the maximum live-load stress is produced by the maximum live load covering the whole span, shall be proportioned for the sum of the dead-load, live-load and impact stresses, on the basis of the allowable unit stresses, f, given for tension or compression, as the case may require. This applies generally to chords and end posts. With the correct section thus found and a total stress, $s' =$ (dead load) $+ 2$ (live load) $(1 + I)$, find the unit stress, f', resulting from 100% overload in the live load; and also find the factor, $k = \frac{f'}{f}$ (always less

than 2), which represents the ratio of increase in the unit stress, f, due to 100% overload. This factor, k, will necessarily be a constant for all members of this class. The impact, I, will be $\frac{165}{l+150}$ for railroad bridges.

Members subjected to dead- and live-load stresses of the same or opposite character, and in which the live-load stress is produced by a partial loading of the span, as for web members generally, shall be proportioned for the algebraic sum of the dead- and live-load stresses plus impact, using a unit stress, kf, where f is the allowable unit stress in tension or compression, as the case requires. Where a reversal in live-load stress is possible, the sectional area should be computed separately for each combination with the dead-load stress, and the larger area will govern the design.

A structure designed in this way will have a minimum factor of safety of 2 on the elastic limit for the assumed live load, and will be uniformly safe for an overload of 100%, in the live load. The unit stresses for the overloaded condition will thus approach the elastic limit for short spans wherein the dead-load stresses are small compared with the live-load stresses. The following example will illustrate the method.

Example.—Given, a single-track span of 452 ft., with 16 panels. (Intermediate span of the Memphis Bridge.) Compressive stresses are negative.

Top chord, $U_6\ U_8$

Dead-load stress	=	— 1 200 800 lb.
Live-load stress	=	— 889 500 "
$I = 0.275$.....	=	— 244 500 "
Total s.....	=	— 2 334 800 lb.

$$\text{Area required} .. = \frac{2\,334\,800}{15\,650} = 149.3 \text{ sq. in.}$$

$$f' = \frac{3\,468\,800}{149.3} = -23\,260 \text{ lb.}$$

$$k = \frac{f'}{f} = \frac{23\,260}{15\,650} = 1.485.$$

Diagonal, $U_8\ M_7$

Dead-load stress	=	— 20 100 lb.
Live-load stress	=	— 111 900 "
$I = 0.408$.....	=	— 45 700 "
Total s.....	=	— 177 700 lb.

Mr. Molitor.

$$\frac{s}{f} = \frac{177\,700}{10\,675} = 16.64 \text{ sq. in.}$$

$$f' = k\,f = 1.485 \times 10\,675 = 15\,850 \text{ lb.}$$

$$\text{Area required} = \frac{335\,300}{15\,850} = 21.15 \text{ sq. in.}$$

$$\frac{335\,300}{16.64} = 20\,150 \text{ lb.} = 1.89\,f$$

This shows that, for double the live-load stress, the unit stress in the top chord was increased 1.485 times; and, for the post, $U_8\,M_7$, the same overload would have increased the unit stress 1.89 times on the basis of 16.54 sq. in. of area. The actual area required by the foregoing specification is 21.15 sq. in. This same post also receives a counter stress in tension equal to the compression, but, as the dead-load stress is compressive, the counter stress did not give the maximum gross area.

Returning to the question of fatigue, which is merely a phenomenon of over-stress, and not particularly due to repetition of stress, the writer quotes the following:*

"*Fatigue of the Material.*—Based on the classic experiments of Wöhler (1859-1870) which were continued by Professor J. Bauschinger, a formula was proposed by Launhardt (1873) and later modified by Weyrauch, aiming to apply the principles of the fatigue of material to the design of bridge members.

"Wöhler's law states that for a large number of repeated load applications, rupture of a material is produced under stress which is below the ordinary (static) breaking strength of that material. The conditions under which Wöhler's experiments were made differ so radically from those attending the actual operating conditions of bridges, that it is questionable whether any one is justified in applying the Launhardt-Weyrauch formulæ to bridge designs.

"Wöhler's load repetitions followed in quick succession and were continued without interruption (several million times) until failure was produced. Bridge members are subjected to a repetition of stress which is always followed by a rather long period of rest, and few structures, even under the heaviest traffic, are retained in service long enough to receive several million applications of the moving load. Also, a well-designed bridge is never calculated for stresses approaching even the elastic limit, while Wöhler bases all his observations on stresses exceeding this limit.

"In addition to these facts, modern experiments made under conditions which correspond quite closely with bridge practice, though limited in extent, point uniformly against the existence of fatigue in bridges.

"The above mentioned Launhardt-Weyrauch formulæ have been extensively used in designing bridge members and are still retained in

* From "Kinetic Theory of Engineering Structures," published 1910, p. 265.

many specifications. However, this practice does not seem justifiable, especially when allowance is made for impact and secondary stresses generally. Mr. Molitor.

"The fatigue formulæ undoubtedly served a good purpose in the days when so many important factors were neglected, but at present the aim should be to make proper allowance for all the known stress elements and thereby reduce the 'factor of ignorance' to a minimum."

One hundred trains per day would give 3 600 000 load applications in 100 years; and a sample of wrought iron required 10 150 000 repetitions of a load of 35 000 lb. to produce failure.

As material undergoes a permanent set when stressed above the elastic limit, it is quite probable that such an excessive stress, if maintained sufficiently long, will produce failure. The great number of repetitions necessary to produce failure is undoubtedly due to the very short duration of each stress application.

Of far greater importance is the uniformity of bridge steel, which in the present state leaves room for much improvement. The writer refers particularly to such defects as piping and segregation, and those who may be interested in this matter are referred to his discussion of the paper by J. A. L. Waddell, M. Am. Soc. C. E., entitled "The Possibilities in Bridge Construction by the Use of High-Alloy Steels."*

CLEMENT E. CHASE,† JUN. AM. SOC. C. E. (by letter).—Mr. Prichard's long experience with the practical manipulation and use of iron and steel, and his very thorough knowledge of the results and significance of past tests on these metals, have given him an unusual insight into their nature. It is because steel is the most important engineering material of construction and because this paper deals with the fundamentals governing its behavior in use, that it is so valuable a contribution. There is a great multiplication of tests in these days, but too often they only serve to pile up a mass of loosely connected, superficial data. Lacking a framework of sound theory to which to adjust the test data, much of the value must be wasted. Long before the entire truth is known (if it ever is) about any subject, it is possible to establish a working theory, in the light of which the results of each experimentation should be examined and the theory added to, strengthened, or modified accordingly. Mr. Chase.

The theory underlying heat action on metals is in common use in America to check and explain in this way the results of all heat treatments, but, to the writer's knowledge, this is practically the first reference in American engineering literature to the theory of strain action, or what is called the "mechanism of plastic deformation." The importance of this theory to the engineer can hardly be over-estimated. Its development was due mostly to a small group of English physicists,

* *Transactions*, Am. Soc. C. E., Vol. LXXVIII, 1915, p. 1.

† Pittsburgh, Pa.

Mr. Chase.

Sir Alfred Ewing, Rosenhain, Humfrey, and Beilby, whose work in this line has only lately begun to be appreciated at its true worth. Their investigations led them into a hitherto unknown field—on the borderland between pure science and practical engineering—opened up by the application of the microscope to the examination of metallic structure. The first paper by Ewing and Rosenhain, announcing the discovery of the basic phenomena of the "slip bands", was published in 1900.* They then advanced the proposition that deformation under strain took place by slippage in each crystalline grain, along the cleavage planes, much as a pack of cards can be distorted without changing the shape of the individual cards. This view of the significance of the slip bands was attacked by continental scientists, and was defended in a series of able papers.† No one who reads these can help but have a feeling of great admiration for the resourcefulness, straight-thinking, and experimental skill with which these men proved their contentions and upheld their important theory. Dr. Rosenhain, who is now Superintendent of the Metallurgy Department of the National Physical Laboratory of Great Britain, last year published an excellent book in which this work is summarized.‡ Recently, American metallurgists have devoted some space in their books to the effect of strain on structure, and a new book§ by Professor Henry M. Howe, of Columbia University, devotes one of two parts to this branch of the science of metallography. In his preface, Dr. Howe says,

"The usefulness of steel really results from its resistance to deformation and its power to endure limited plastic deformation. Hence a knowledge of the mechanism of this deformation and of the way in which steel in part resists deformation and in part accommodates itself to it, may in time disclose the essence of its power of resistance and accommodation. To understand this essence is to be the better prepared to approach the problem of fitting the metal for service, not empirically alone, but also scientifically."

In the writer's opinion, this study is not one of which the metallurgists should be allowed to have any monopoly. Understanding and use of it will be of even greater value to engineers. Mr. Prichard approaches the matter from the attitude of the structural engineer. Following his thought, one is led into the subject from the familiar direction of physical tests of metal. The English metallurgists reached their conclusions largely from what they saw in the microscope. Mr. Prichard has come to the same point through searching for the significance of engineering test phenomena. It has been the writer's privilege to follow to some extent the preparation of this paper, and he regards it as worthy of record that Mr. Prichard's theory was

* *Philosophical Transactions*, Royal Society, Vol. 353A.

§ "The Metallography of Steel and Cast Iron".

formulated, practically in its present shape, before the work of Beilby on the mobile and amorphous states of metal was known to him. The significance of this is that it shows how thorough study of the problem from either the engineering test direction or the micro-metallurgical direction leads to the same conclusion. Mr. Chase.

Mr. Prichard states that the deformation of metals in tension and compression is in reality caused by failure to resist shear. This conclusion comes irresistibly from a study of the microscopic phenomena of slippage, which is essentially a shear action. It must also be the conclusion of any one who has watched thoughtfully the formation of the lines, referred to by Mr. Prichard, on the mill scale of tensile tests. In regard to these lines, the writer cannot agree that they usually take a direction of about 26° 34′ to a plane normal to the direction of pull. It has been his observation that this angle is more nearly 45 degrees. Tensile tests of hooping and flat steel, however, fracture usually at an angle which is about 26° to this plane. Mr. Prichard's hypothesis, on pages 1437-38, as to the manner in which the particles in the crystalline grains slip, gives a simple picture of the action. Actually, the slips in the grains occur in any direction, depending on the orientation of the grain to the shearing stress and the location of the most favorably disposed cleavage planes, and in at least as many as three directions in the same grain under severe overstrain.

Fig. 3, representing the necking down of a tensile test piece, is subject to the criticism that the actual necking of test pieces gives much more support than this figure does to the conception that the failure is by shear in ductile metals. Fig. 10 shows the tension fracture of a test bar of structural steel. The necking of the piece was parallel to the line, *S-S*, which is also parallel to the fracture. This line makes an angle of about 28° 40′ with the axis of the test piece. It will be noted that slippage occurred along the line of fracture, or the zone of fracture, to such an extent that one-half of the test is displaced $\frac{1}{16}$ in. to one side. Fractures exactly similar to this have been noted in full-sized eye-bar tests. The more symmetrical "cup" fractures of tension bars also give evidence of this failure by shear.

The writer agrees with Mr. Prichard in what he says as to the elastic limit and yield point, and believes that there would be less confusion surrounding these terms if there was more appreciation of the significance of the phenomena of plastic deformation that this paper deals with. We now have "true" elastic limit, proportional elastic limit and yield point—and others. It seems to the writer very probable that there is no "first permanent set" without a corresponding variation from proportionality—and that the two limits are, in fact, coincident. It is only the fact that delicate extensometers can detect slight permanent sets at a lower point (often due to initial strains)

Mr. Chase.

than the eye can determine any regular breaking away of the stress-strain curve, that gives these two points apparently different values. The writer believes Mr. Prichard is right in saying that it is only that elastic limit which is at the beginning of the general yield that has any real significance. To indicate the method of locating the limit, the qualifying words, "by set", or, "by proportionality", might be used.

Clear light has been thrown on the long-debated question of "crystallization" and fatigue by the men to whose work Mr. Prichard refers on pages 1452 and 1455. The misunderstanding, between those who believe in "crystallization" of metal in service and those who do not, is mainly one of terms. "Crystallization" would have it that metal becomes coarsely crystalline under vibration or long-continued severe

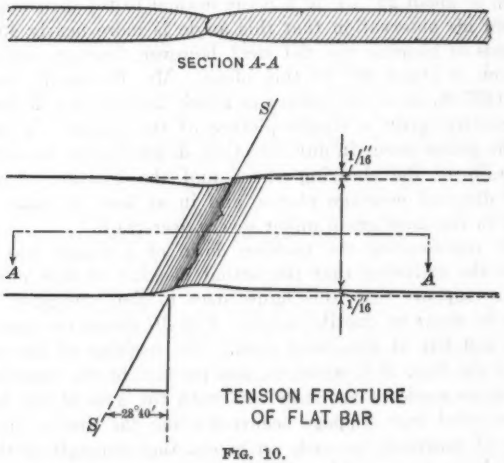

FIG. 10.

service—and points to the fracture of the metal in proof. Now, it is not true that metal becomes crystalline, for it always is crystalline—but it is true that under stresses approaching the elastic limit if repeated, or half that limit if alternated, an internal change takes place in the metal that eventually manifests itself by failure. That change is the development of internal slips into internal cracks, and results finally in a sudden snapping of the metal, with no showing of ductility, and with a fracture that satisfies the eye as crystalline. The deterioration that the layman insists on is true, if not as easily caused as he imagines —the theory as to its mechanism, that he implies in the term "crystallization", is not true. No indication has ever been found of any growth of the crystal size of steel at atmospheric temperature. However, for

those who declare offhand that the idea of crystal growth in cold steel is preposterous, there may be food for thought in the fact, which Mr. Prichard has mentioned, that in lead such crystal growth does occur under certain conditions at atmospheric temperatures. The microscope gives an explanation of the comparatively coarse size of the facets often found in a fatigue fracture. It is the progressive spread of the internal cracks in a plane through several crystalline grains while the deterioration is in progress. Mr. Chase.

HENRY S. PRICHARD,* M. AM. SOC. C. E. (by letter).—Mr. Chase, after describing the fine achievements of the English physical metallurgists, states: Mr. Prichard.

"In the writer's opinion, this study is not one of which the metallurgists should be allowed to have any monopoly. Understanding and use of it will be of even greater value to engineers. Mr. Prichard approaches the matter from the attitude of the structural engineer. Following his thought, one is led into the subject from the familiar direction of physical tests of metal. The English metallurgists reached their conclusions largely from what they saw in the microscope. Mr. Prichard has come to the same point through searching for the significance of engineering test phenomena."

In studying the phenomenon of plastic deformation of steel and iron, not through the eyepiece of the microscope, but by applying mechanical principles to the ordinary physical tests, the writer conceived of the flow by which the deformation is accomplished as consisting of the sliding relatively to each other of perfectly elastic solid particles separated by thin highly viscous mobile or liquid films. The investigations of the English physical metallurgists, as described by Messrs. Chase and Irwin, have led to precisely this conclusion. Under refined and ingenious methods of microscopical research with great magnifications the little masses or grains, as they are called, which are disclosed by ordinary microscopical examination, are shown to be compound, and have been resolved into numerous crystalline elements which are in themselves little crystals, and constitute the fundamental grains of the solid portions of the metal, which slide relatively to each other during plastic deformation.

As to the theory formulated by Mr. Irwin, and attributed by him to the writer, to the effect that these aforementioned compound grains remain perfectly elastic during plastic deformation, the writer had not the slightest intention of promulgating any such idea; on the contrary, it may be noted, incidentally, that, in referring, on page 1437, to what is seen under the microscope, he did not state that the slips between the sliding particles appeared as sharply defined lines

* Pittsburgh, Pa.

Mr. Prichard.

between the grains, but as sharply defined lines on the polished surface of each grain. The writer, however, was dealing primarily with the principles involved and not with the precise inner structure of the metal. It was not necessary, and he did not choose, to complicate the application of the principles by introducing details of structure; but he hoped that the details of structure would be discussed, and he is pleased that this phase of the subject has since been so ably handled by Mr. Irwin.

The current theory of plastic deformation included in the paper is useful in explaining the effects of over-straining iron and steel, and is destined to become of service in guiding the course of future experimentation.

The theory, as Mr. Chase explains, is not very old, and has only recently been presented to American engineers. That there should be some criticism and opposition is natural.

Phases of the theory have been investigated independently from different standpoints. Writers on theoretical mechanics have proposed three theories of the breakdown of the elastic resistance of an isotropic solid, as follows:

First.—That the elastic limit is reached at a certain intensity of direct stress;

Second.—That the elastic limit is reached at a certain intensity of linear strain;

Third.—That the elastic limit is reached at a certain intensity of shear. This was proposed by Mr. J. J. Guest,* and is the latest of the three theories.

Mr. Moore states that the paper quotes Mr. Hancock's tests as a proof of the maximum shear theory, and questions whether they are a confirmation. The word "proof" is a little too strong. The paper, in referring to plastic materials, made the statement:

"That shear is the critical consideration is supported by experiments and analysis of J. J. Guest, Professor E. L. Hancock, and others."

The comparative results of Hancock's tests† (of steel) are as given in Table 8.

After considering the results of many tests, the writer reached the conclusion, held by most authorities, that brittle or comminuible materials, under simple compressive loads, fail by shearing on planes at certain definite angles with the direction of the load; and, in comparing the theoretical and the actual planes on which slipping oc-

The writer reached the conclusion that plastic materials under simple tension or compression slide on slippage or gliding planes, from a study of the phenomena displayed in tests and, later, from Sir J. Alfred Ewing's account of his microscopical examinations. The conclusion that it was the shearing components of the simple tension or compression, acting on planes of maximum shear and uninfluenced by the component normal to these planes, was drawn from the fact that the elastic limit is the same in both tension and compression. Hancock's experiments on tubes support the theory that shear is critical. His experiments on solid sections seem to

* As given in Johnson's "Materials of Construction", p. 24.

Mr. Prichard.

favor the theory that stress is critical, but, in the writer's judgment, the computed results are much in error and untrustworthy. For solid sections, in such cases, the elastic limit is not well defined, and this and other departures from the assumptions tend to indicate stresses and shears much higher than the actual.

The writer's conception of shear is by no means "peculiar", as Mr. Jonson suggests. On the contrary, the conception of shear, as given on page 1436, is so orthodox that it can be found in any textbook on mechanics.

It may be well at this point to define shear:

"An action or force which causes or tends to cause two contiguous parts of a body to slide relatively to each other in a direction parallel to their plane of contact" (Webster).

Before the elastic limit is reached, shear only tends to cause contiguous parts of a body to slide relatively to each other.

According to Mr. Jonson, flow begins when the shear reaches the elastic limit, and flow takes place "only when the shear exceeds the elastic limit." This is in exact accord with the paper (page 1440).

The important differences between Mr. Jonson and the writer are in regard to what takes place beyond the elastic limit, and are two in number:

First, the writer contends that, beyond the elastic limit, the shear causes "contiguous parts of a body to slide relatively to each other in a direction parallel to their plane of contact," and that flow is the combination of a multitude of such slidings of numerous small parts accompanied by such rotations of the parts as may be necessary to continuity and alignment; but Mr. Jonson contends that the "use of the words 'sliding' and 'slipping' in connection with flow seems to be unfortunate, because flow is something entirely different from slipping. Flow consists of an indefinitely extended, angular deformation".

Second, the writer contends that part of the work done by the load after the elastic limit is reached consists in liquefying films of metal between the sliding surfaces, or, as Beilby puts it, conferring on them by purely mechanical movement the "mobility of the liquid state" (pages 1440 and 1460); Mr. Jonson, on the other hand, states:

"The author seems to conceive of the flow which takes place in ductile metals when stressed beyond the yield point as if it were due to a change in the metal from the solid to the liquid state. The energy required to bring about this change of state he seems to regard as a part of the work done by the load. This, however, is not in accordance with the facts. All the work done by the load previous to the beginning of flow is stored in the test piece as elastic energy."

Mr. Chase, after referring to the fact that deformation of plastic metals in tension and compression is caused by failure to resist shear, states: Mr. Prichard.

"This conclusion comes irresistibly from a study of the microscopic phenomena of slippage, which is essentially a shear action. It must also be the conclusion of any one who has watched thoughtfully the formation of lines, referred to by Mr. Prichard, on the mill scale of tensile tests."

(Incidentally, it may be stated that Mr. Chase considers that for these lines the angle of 26° 34′ to a plane normal to the direction of pull is too small. This angle was given in the paper as a rough approximation obtained by averaging the tangents of 0° and 45 degrees. A slippage plane, at an angle of 45° with a plane normal to the direction of the force, may make any angle between 0° and 45° with the surface of the test piece. The writer, since the paper was presented, has computed the average of the angles cut out by all possible intersections as nearly 32½ degrees.)

The facts discovered by the "small group of English physicists", to whom the development of the theory of the "Mechanism of plastic deformation" is mainly due, are so pertinent that it may be well to let these physicists tell the story. Mr. Beilby's account of what followed "The discovery that layers of a solid many hundreds of molecules in thickness can have a mobility of the liquid state conferred on them by purely mechanical movement" is quoted in the paper (page 1460).

Sir J. Alfred Ewing's account of the slips which take place within the crystalline grains of metal after the elastic limit is passed, is taken from a copy of the 1912 May Lecture before the Institute of Metals on "The Inner Structure of Simple Metals", with which the author recently favored the writer. The photo-micrographs referred to are reproduced by the authority of the Institute of Metals and Sir J. Alfred Ewing.

"My intention to-night is first to remind you briefly of some of the things that the microscope has taught us regarding simple metals, and then to go on to some more or less speculative considerations based on that knowledge. I propose to confine myself definitely to simple metals—that is, metals which behave as pure metals behave, leaving untouched the large and complicated subject of the alloys. Alloys present complexities that would only distract attention from the particular points which I wish to bring before you. Without those complexities we shall find the matter difficult enough.

"Some apology is due to the experts in the audience for presenting facts with which they are already familiar, but probably the audience includes some who are not experts, and in any case it is convenient to recapitulate a little of our positive knowledge before entering the region of speculation.

Mr. Prichard.

"Generally speaking, when we wish to apply the microscope to the examination of metallic structure, we begin by polishing the surface of the metal so as to remove those inequalities which would embarrass the use of the microscope, especially at high powers. As Dr. Beilby showed in the admirable May Lecture he gave last year, the process of polishing itself affects the constitution. It makes the metal on and near the surface entirely different in character from the metal within. It produces, according to his view—which, I think, is now generally accepted—an amorphous layer in contradistinction to the crystalline structure which, as we shall presently see, is revealed when that amorphous layer is removed. Consequently, what we have first to do after polishing is to remove the superficial layer before we can really see the normal characteristics of the structure, and the usual manner in which that layer is removed is by a light chemical attack, a slight etching with an acid or some other substance. Occasionally, we may resort to other means of removing the layer. An interesting method which is sometimes available is to heat the metal sufficiently to make the surface layer sublime away.

"When we lightly etch the surface of a metal, what do we see? In general we see an appearance such as is illustrated in Fig. 1, Plate I. This is a photomicrograph taken by Dr. Rosenhain of part of the surface of a bar of Swedish iron, magnified 150 diameters. A very similar appearance is presented by other metals. The surface is seen to be composed of a large number of separate grains, irregular both in size and shape, and also irregular as regards the character of the boundaries. Sometimes these are straight and sometimes curved. The shapes of the grains are as irregular as the counties in a map of England; their boundaries depend, like those of the counties, on historical conditions, as we shall see by and by.

"Suppose now that we carry the etching a little further (Fig 2, Plate II). We discover that the grains can be distinguished not merely by these irregular boundaries. A difference of texture begins to manifest itself between one grain and another; some grains are very bright, some are more or less dark, and some are very dark. If instead of illuminating the surface directly from above, as is the case in Fig. 2, we throw the light from one side, we discover that the same grain which appears bright under one condition of illumination becomes dark under another. Compare Fig. 3, Plate II, with Fig. 2.

"These are two photographs, for which I am indebted to Dr. Rosenhain, showing the same part of the surface of one metal under two different conditions of illumination. In Fig. 2 the light comes directly from above; it strikes the surface perpendicularly, and is reflected up into the microscope. In Fig. 3 the same grains are illuminated by light coming from one side. It will be observed that there is no difficulty in identifying the same grains in both; and that grains which are very bright under the first illumination become dark under the other. If we move the source of light to another side, or turn the specimen round, so as to alter the direction from which the light falls upon it, we find the grains vary in brightness in the most remarkable manner, sometimes flashing out brilliantly and sometimes becoming almost entirely dark. This is true of all metals. These

"FIG. 3. PLATE II.—SAME SURFACE AS FIG. 2, BUT WITH OBLIQUE ILLUMINATION."

photographs are of iron, but we find gold, silver, copper, lead, and so forth, exhibiting precisely the same general characteristics. Mr. Prichard.

"Examination of the etched surface under a high power shows that this difference of texture is really due to a multitude of little facets or tiny plane surfaces in each grain which are causing the general surface of the grain to reflect light in a particular manner. They are acting like a multitude of little mirrors all facing one way. These facets are parallel in any one grain, but have different inclinations in the different grains.

"In Fig. 4, Plate III, we have a photograph of a grain of iron, not very deeply etched. A part of a single grain occupies nearly all the photograph under a power of 800 diameters. You observe that over the grain, here and there, are a number of pits which are clearly geometrical in form; they happen to be nearly square in this particular case. In some places a number of pits have run together forming a black irregular patch, but in other places you can see the individual pits quite clearly. These pits are formed in the process of etching.

"Under more favourable conditions, with deeper etching, the whole surface becomes covered with such pits. Fig. 5, Plate III, is a photograph published a good many years ago by Dr. Stead, which shows very clearly what it is that gives rise to what I have called the texture of the grain. In the former example you had only isolated pits, but in this one the appearance is such as would be presented if we were to take a great mass of brick work and pick out the superficial bricks all over it, so as to reveal the character of the structure as built up of brickbats. That, in effect, is what happens in the etching of a metal.

"I do not know any example which gives a clearer indication than this does of what causes the difference of texture in the surface of these grains, nor one that indicates more plainly the real nature of their structure, as developed by etching. One can see unmistakably how the surface of the grain consists of a multitude of geometrically similar pieces, parallel to one another, so that their corresponding facets are all oriented one way. They are oriented in different ways as we pass from grain to grain, but in any one grain they face one way, and in consequence of that the light which falls on the grain is reflected in a perfectly uniform manner over the whole expanse of that grain, although it is reflected in a very different manner from the surface of any other grain. Over each grain the brightness is uniform, because the little surfaces are acting equally as regards the reflection of light.

"From this it is an easy step to infer that throughout the whole volume of any one grain there is an assemblage of pieces, which we may think of as the "brickbats" or structural units that build up the grain, all facing one way in the one grain, but facing different ways in different grains. Fig. 6, Plate IV, is another example, a piece of etched tin-plate, exhibiting the same characteristics. It shows a portion of two grains of the thin layer of tin with the boundary between them, and the difference of brightness is very marked. They are both exposed to the same light, but they reflect different amounts into the microscope. The reason is that the little facets on one are much more favourably directed for the purpose of reflecting the light back to the microscope than are the facets on the other.

Mr. Prichard.

"One might multiply illustrations all pointing to the same fact, namely, that the etching has revealed a definite geometrical structure within the grain by removing, as it were, a few of the superficial brickbats, leaving cavities and protuberances of a geometrical form. The conclusion is simply this, that every one of these grains is in reality a crystal. Notwithstanding the irregularity of the boundary it has the true property of a crystal, the uniformity of internal structure which is the characteristic of a crystal. It is, to use Kelvin's phrase, a 'homogeneous assemblage' of structural units which is put together with greater regularity than any structure built up of definitely formed brickbats." * * *

"A very important point about metallic structure is that we find true crystal grains not only in metals in the cast state but also in metals in other states, metals which have been wrought, which have been shaped by working even in the cold condition, and also in metals that have been worked in the cold condition and have afterwards been annealed by bringing them to such a temperature that a rearrangement of the grains has taken place. Whether we deal with them in the cold condition or in the annealed condition, we still find the same general characteristics, still the same granular structure, and still the same plain evidence that each grain is in reality a crystal.

"Take, for instance, a bar that has been shaped by being passed through a rolling-mill in the cold state. One of the photographs already shown (Fig. 4, Plate III) is part of the transverse section of a cold-rolled iron bar, rolled down from a comparatively large diameter, so that the individual grains within the bar have suffered tremendous distortion in the process of rolling. The greater part of the field is covered by a single crystal. Over its whole surface there are geometrical pits. When it was examined very carefully in the research by Dr. Rosenhain and myself we found that these pits were parallel all over the crystal notwithstanding the tremendous distortion it had undergone. It was clear, therefore, that the regular parallel grouping of the structural units or brickbats had in some way or other been preserved during the process of severe straining.

"The point is further illustrated if you examine in the microscope a specimen of metal that has been broken in a testing machine. Take a fairly plastic metal, such as iron or mild steel, which stretches a good deal before it breaks. If you polish and etch the side of the bar near the fracture, where a considerable amount of extension has taken place, you will find that the metal there consists of grains similar to those you have already seen, but with this difference, that these grains are all elongated in the direction of the stretching. Their shapes may be still very irregular, but there is clearly a predominating greater length in the direction along the bar, as compared with the transverse direction. The stretching the specimen underwent before it broke has elongated each grain, but its granular character persists.

"The crystalline constitution of the grains, then, survives severe straining. How does it do so? That is a question Dr. Rosenhain and I set ourselves to answer. We tested specimens of metal by straining them actually under the lens of the microscope and observing what happened during the process. The specimen was a thin strip of sheet metal, which was strained in such a manner that the same crystals

"FIG. 4, PLATE III.—IRON, SHOWING PITS PRODUCED BY ETCHING. MAGNIFIED 800 DIAMETERS."

4 PAPE

were kept in view the whole time. In Fig. 1, Plate I, we had a specimen of iron lightly etched. This was subsequently strained by tension, but the photograph of Fig. 1 was taken before the straining began. In Fig. 10, Plate I, we have identically the same grains after a slight amount of straining—enough to carry it beyond the elastic limit, but not much beyond. If we compare those two accurately by applying compasses and measuring the lengths of the grains, it will be found that in Fig. 10 each grain has become a little stretched in one direction and a little shortened in the transverse direction. But that is not the main difference. The main difference produced by the straining is that over the surface of each grain a number of curious black lines have appeared, almost like the crevasses of a glacier, lines which are substantially straight and substantially parallel. It is in virtue of these lines that the plastic strain of the crystal grain has happened. These lines mean not that crevasses are formed, for there is no rupture of continuity, but that there has been shearing at a corresponding number of internal surfaces, that the crystal grain has behaved as a pack of cards behaves when you try to make it alter its form. The pack of cards becomes strained by the slipping of one card on the other, of each layer on its neighbor. In precisely the same way the crystals of metal become strained by the slipping of the little brickbats of one layer on those of the adjacent layer within each grain. The result is that on the polished and etched surface little steps are formed by the slipping, and it is these little steps that constitute the black lines you are now looking at. They are narrow bands rather than lines; Dr. Rosenhain and I, when first we discovered them, called them 'slip bands'." * * * Mr. Prichard.

"Clear proof that the slip lines are really little steps was furnished by testing the effect of oblique illumination. It will be obvious that, if the theory is correct, it should be possible, by throwing the light from the side, to get the little step which was dark in the first instance to shine up brightly. We have only to choose an appropriate direction from which the light should come in order that the step may reflect it up into the microscope. That has been done in this slide. Here are illustrations of what Dr. Rosenhain and I found when we made that experiment. In Fig. 13, Plate VII, we have several grains of a strained specimen of lead illuminated by light falling very obliquely from one side. The light is so placed that some of the slip lines or slip bands are bright, through reflection from the little steps up into the microscope. The light is falling on all the grains alike, but only one is visible, because none of the slip lines on the others are favourably situated for reflection into the microscope. Now we shift round the direction of the illumination (Fig. 14, Plate VII): another crystal has its slip lines brilliantly illuminated, and at the same time the one that had its lines illuminated before has now become dark.

"Fig. 15, Plate VI, is a photograph of the system of slip lines on a small part of a single lead crystal under a magnification of 1 000 diameters. You can see that the slips have produced small differences of level, and it is apparent that they have taken place successively in the different planes, so as to result in a compound system of steps.

"Dr. Rosenhain gave subsequently a further demonstration by obtaining a transverse section of the steps formed by slipping. To do

Mr. Prichard.

this he strained a piece of iron to form the lines, and then deposited a thick layer of copper upon it by an electrolytic process; finally he cut a transverse section through both the iron and the copper covering, and polished that for microscopic examination. Under a high power it was seen that the surface between the two metals had upon it a number of little definite parallel steps, which corresponded to the slip lines produced by straining the iron.

"We conclude, then, that the plastic yielding of metals under strain is due to slips occurring on the gliding planes of the crystal grains. This notion gives a key to plasticity in metals. It is not going too far to say that any amount of distortion can be accounted for by slips of this kind without requiring the continuity of the crystalline structure to be interrupted."

The continuation of this story of the "Mechanism of plastic deformation" is by Dr. Rosenhain:

"If we realise the true nature of this phenomenon of deformation by slip, we see at once that it throws a flood of light on the behaviour of metals under stresses sufficient to bring about plastic strain. If such plastic strain occurs solely by slip, then the truly crystalline nature of the metal should remain unaltered by the straining process. We have already seen that strained, *i. e.*, elongated crystals, still exhibit the essential characteristics of crystals, so that, broadly speaking, this generalisation is correct. But there are a whole series of other phenomena connected with the process of plastic strain which would be extremely difficult to explain satisfactorily on any theory which required the structure of metal to remain perfectly crystalline, even when very severely strained. The circumstance that a metal is hardened by strain, in the sense of having a much higher yield-point and limit of elasticity, and even a higher breaking stress, is one of these facts. These circumstances have led the author to adopt a view put forward in the first place by Beilby [p. 100], to the effect that while plastic deformation—and although we have merely discussed its occurrence in connection with tensile strain, its nature and mechanism is the same whatever the system of forces which have brought it about—takes place by slip on the gliding planes of metallic crystals, yet that the act of slipping is accompanied by something further. Just as the rubbing action of polishing produces on metal surfaces a thin layer of altered, amorphous material, so we may well expect that the sliding over one another of adjacent slip surfaces will produce a local disturbance of molecular arrangement. If the slip is slight, then it probably happens that this derangement is also slight and temporary and that the disturbed molecules are still able to rearrange themselves pretty much in their original system. In such a case the crystalline orientation is not at all disturbed. If, on the other hand, the slip has been more pronounced, the resulting local disturbance will also be more far-reaching, a greater number of molecules will be disturbed, and they will no longer be able to re-arrange themselves in the old crystalline system. A more or less thin layer of amorphous metal will thus be formed on each surface of slip. At first—for a short time—these layers will probably possess a certain degree of mobility, like the surface film which adjusts itself under surface

tension. During this period these layers would act as a sort of lubricant, facilitating further slip on the same gliding planes. After a time, however, when the disturbed molecules have had time to 'set' in the amorphous condition, we should have on each plane where slip has taken place a layer of hard, non-plastic, amorphous metal. These would effectually prevent further slip on that particular set of gliding planes, and the crystals would be limited, in accommodating themselves to further plastic strains, to slip on other surfaces which had not been 'used' in the previous straining. But all the surfaces of *easiest* slip will have been used at the first straining, so that to effect plastic deformation the second time more force would be required. Not only this, but the hard and brittle amorphous films on the surfaces of previous slip would also act as a stiffening skeleton for the whole crystal and thus offer additional resistance to the commencement of fresh slip." * * * Mr. Prichard.

"If we regard cohesion within the body of a crystal as being due to the attractions between layers of adjacent molecules, we can readily understand the continuity of such cohesion acting throughout the entire mass of any one crystal. The forces which are at work in producing cohesion between adjacent crystals must, however, be of a somewhat different character, for it is obvious that the regular arrangement of molecules in oriented layers cannot be carried on through a crystal boundary, while it appears that the actual cohesion between adjacent crystals is stronger than that between different layers of the same crystal." * * *

"In addition to changing their own shapes, the crystals must move relatively to one another. The strength of the crystal boundaries is found to resist such movement, and the slip-bands are found to be arranged in such a way as to minimise the amount of displacement occurring at the actual boundaries. In other words, the metal takes up the new shape imposed on it, as far as possible, by means of slip within the crystals and with as little disturbance as possible of the inter-crystalline boundaries. That there is some definite movement at the boundaries becomes evident if a polished specimen is strained without being previously etched; the effect of the strain at once causes the crystal boundaries to become visible on the surface."*

Structural steel is a mixture in which more or less connected hard grains of an alloy termed pearlite are embedded in a softer matrix composed of grains of iron. The grains of pearlite consist of alternate thin layers of iron (Fe) and cementite (Fe_3C) in the proportion of six parts of iron to one part of cementite. If a specimen of such an alloy is

"provided with a polished surface and is then plastically strained, it will be found that the effect on its surface appearance is almost identical with that obtained by etching—the laminated structure is very clearly revealed. Close examination has shown that what really happens is that slip occurs along, or very close to, the boundaries of the

* "An Introduction to the Study of Physical Metallurgy", by Walter Rosenhain, Superintendent, Metallurgy Department, National Physical Laboratory, pp. 245–247, 257 and 258.

Mr. Prichard.

lamellæ of the two constituents present. When it is borne in mind that these lamellæ are formed by the process of crystallisation, it will be seen that their surfaces must lie on or near to some of the principal crystallographic planes, so that it is not really surprising that slip should occur on these surfaces."*

Grains of iron, as shown by photo-micrographs, are irregular as to size and shape, somewhat as in Fig. 11, except for the grain, *A-B-F-G*, which is drawn of conventional shape for simplicity of illustration. The slipping of the layers of the grain upward and to the right as a result of over-straining is shown in Fig. 12, which is drawn for the grain, *A-B-F-G*, enlarged. A second slippage upward and to the left will make offsets in the first slippage planes, as in Fig. 13. If the layers simply slipped, the grain, as a whole,

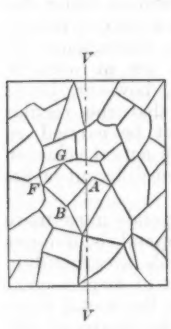

FIG. 11.

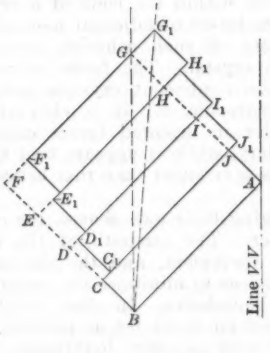

FIG. 12.

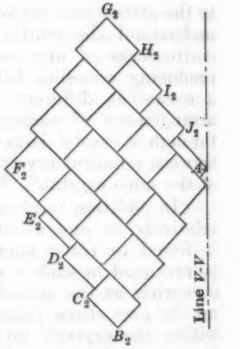

FIG. 13.

would tip to the right on the first slippage and crowd the neighboring grain adjacent to the line, *A-G*, and would tip back again on the second slippage. It is Professor Howe's opinion that the layers simply slip and project into the adjoining grains. He has discussed the matter at some length,† and concludes that the phenomena observed are those which would naturally follow in case there were no such rotation. It seems to the writer, however, that the geometrical necessities of the case require some slight rotation of the layers with each slip. The aggregate angle of rotation might not be great, however, as the rotations from slips in opposite directions tend to balance.

Professor Howe gives a valuable analysis of the effect of the rapid hardening of mobile metal during a test. It is pointed out in

* *Ibid*, p. 261.

† "Metallography of Steel and Cast Iron."

Mr. Prichard.

the paper that such action may take place (page 1450). The writer does not consider that all the metal made mobile or viscous during a test will entirely solidify before the test is completed. Some portion may remain viscous for a while during a rest after being over-strained (pages 1450-51), and for a long while under repeated stresses. Professor Howe's suggestion, that a very important degree of true fatigue may occur, even before sub-microscopic tears form, seems to be in line with this thought and very reasonable.

That there is a temporary fatigue is shown by the behavior of iron and steel for a period after being over-strained. One manifestation is greater deformation under repeated stresses within the primitive elastic limit, as illustrated in Table 9, and under alternating stresses, as shown by a paper recently read before the Royal Society.*

The presence of some viscous metal on the planes of slippage and beneath the polished surface of the test piece would facilitate etching; and its subsequent solidification during a rest or gentle heating would make the test piece more difficult to etch, and thus explain "why after a heating so gentle as to intensify the hardness caused by deformation no traces of the amorphous metal along the slip planes can be detected."

"The explanation of the process of failure by 'fatigue', *i. e.*, under the repeated alternations of a stress which would not cause fracture if steadily applied, is also furnished by the conceptions described above as to the behaviour of a crystalline aggregate under strain. A stress which is to cause ultimate failure after repeated alternations must be large enough to produce a small amount of local yielding in the metal. This may be so small in amount as to be unobservable, even with a delicate extensometer, and in that case the stress would be regarded as lying within the apparent or 'primitive' elastic limit, but the microscopic examination of polished test-pieces under load has shown that the formation of slip-bands in isolated crystals here and there in the metal may and does occur for stresses of this kind. Some crystals, by their shape and the orientation of their gliding planes are unfavourably situated to resist the particular system of stresses which has been applied, and a slight local slip takes place.

* The following is a transcript of a printed abstract, from the paper, furnished to the writer by Professor W. C. Unwin:

"W. MASON. On Speed Effect and Recovery in Slow-Speed Alternating Stress Tests. Communicated by Professor B. Hopkinson, F. R. S."

Repeated cycles of equal direct and reverse torque have been applied to mild steel specimens of tubular form, and systematic measurements made of the range of the corresponding torsional strains. The speed of application of the cycles was varied between 2 and 200 per minute. After a considerable number of cycles at 2 per minute, the range of non-elastic strain was reduced about 50% on change of speed to 200 per minute, the range of torque being unaltered.

Similarly, if a specimen had endured a considerable number of cycles at 200 per minute, the range of non-elastic strain was immediately increased by 50 to 75% at change of speed to 2 per minute. If the latter speed was maintained, the augmented range of strain decreased, quickly at first, then more and more slowly. This recovery is compared with the reduction of range of strain due to a period of rest. The author attempts to account for these variations of strain on the hypothesis of alternate production and hardening of "mobile material in the steel."

Mr. Prichard.

Ultimate strength on sixth loading, 87 170 lb. per sq. in.

If the load remains in steady action, nothing further occurs. If, however, the stress is reversed—*i. e.*, if the metal is being subjected to alternating stress—then this slight amount of slip will also be reversed, particularly as the slip surfaces will still be covered with the temporarily mobile layer of amorphous metal. Such reversal will be repeated with each reversal of the applied stress, and at each successive slip the layer of amorphous material will be increased. After a time, however, by virtue of its temporary mobility, this film of quasi-liquid metal will be squeezed out between the gliding surfaces, and the site of the initial minute slips will develop into a fine crack. As this process continues, that particular crystal soon begins to lose its strength, and additional stress is thereby thrown upon its immediate neighbours, which undergo slip and gradual disintegration in the same way. Ultimately, the crack or flaw thus originated works

Mr. Prichard.

its way across the entire section of the metal, and failure of the piece results. If the action has been fairly rapid, *i. e.*, if the stress was high enough to produce somewhat rapid disintegration by repeated reversals of slip, the resulting fracture exhibits the crystal faces upon which slip has taken place as a number of bright facets resembling those produced in a 'brittle' shock fracture, and it is this appearance which has led to the mistaken idea that alternating stresses cause metal to 'become crystalline'. Actually, as we have seen, the metal is crystalline from the beginning, never really 'fibrous', and the 'fibrous' or 'crystalline' appearance of the fractures depends on the mechanism of fracture, and not on any change in the crystalline structure of the metal.

"The explanation of fatigue fracture which has just been given, although it has been deduced from the general character of plastic deformation by slip, was first given by Ewing and Humfrey, as the result of direct experimental observations in which they watched the formation of slip-bands in certain crystals, and their gradual growth into cracks on the polished and etched surfaces of pieces of Swedish iron submitted to the Wöhler test."*

It is stated in the paper that experiments by Wöhler during the period, 1858-1870, indicate that the elastic limit can be raised when part of the stress is constant and part constantly repeated (page 1460); Launhardt devised a formula, following Wöhler's experiments (page 1461); but such formulas are not applicable to the design of bridge members, for the reason that the deformation beyond the yield point is ruinous (page 1462). In epitomizing these facts in the Synopsis (page 1433), the writer hoped to emphasize the caution against relying on any increase above the primitive elastic limit, in designing tension and compression members; and he did not desire to imply, by the statement quoted from the Synopsis by Mr. Stanton, that the strength can be raised above the yield point by repeated stresses "varying from zero to an upper limit."

Mr. Stanton states "that the phenomenon of repeated loadings of a structure from zero to an upper limit is only a particular case of cyclical variations of stress", and he refers to a "valuable paper" by Mr. Bairstow. Mr. Bairstow's conclusions in the paper referred to are as follows:

"It is found that, after a sufficient number of repetitions, iron or steel is capable of adjusting itself to variations of stress, cyclically applied. When this adjustment is complete, the specimen is found to have become perfectly elastic throughout the whole cycle, and fatigue does not occur.

"This adjustment to a given cycle is possible because the limits of elasticity are not fixed, but can be raised or lowered by repetitions of stress.

* "An Introduction to the Study of Physical Metallurgy", by Walter Rosenhain, pp. 253–254.

Mr. Prichard.

"During the adjustment of the elastic limits to a given cycle of stress a change of length occurs in the specimens, which is the same as the extension observed in an ordinary tensile test when the yield stress is exceeded. For cyclically applied stress a similar extension occurs, even when the maximum stress in the cycle is less than the static yield stress.

"The greater the extension of the specimen during adjustment, the greater are the amounts by which the elastic limits are raised.

"The power of adjustment is limited, and if the range of stress in the imposed cycle is sufficiently great, the specimen becomes or remains inelastic, and work is performed during each cycle. This work is expended in moving portions of the crystals relatively to one another, and is probably associated with microscopic slip-lines which gradually develop into cracks, ultimately causing fracture of the specimen."*

In addition to the experiments on repeated stresses to which Mr. Stanton refers, Mr. Bairstow made some successive tests in tension and compression on axle steel (which had first been subjected to a cycle of alternate stresses of sufficient duration to secure equal elastic resistance of the metal to tension and compression), and obtained the following results:

"Following a final load of 18.6 tons per sq. in. in tension, the specimen was heated in boiling water for 15 minutes. Test No. 2 showed that the specimen was still elastic at the same load. In compression the limit was reached at about 8.5 tons per sq. in., and the load was continued to 13.28 tons per sq. in. Recovery was again produced, and it was then found that the elastic limit in compression had been raised at least to 13.28 tons per sq. in., but that the tensile elastic limit had fallen to 13.0 tons per sq. in. By alternate heating and testing, the elastic limits were moved about very considerably, but always with the condition that if the tension limit was raised the compression limit was depressed, and *vice versa*."†

Bauschinger and others have tested steel and iron alternately in tension and compression, with somewhat similar results. In the above quoted alternate tension and compression tests by Bairstow, the range of stress between the elastic limits in tension and compression remained nearly constant at about 27 tons per sq. in., against an original yield point of 24.9 tons per sq. in. On the other hand, some re-tests of eye-bar steel at the Watertown Arsenal, after a rest of 3 years and 3 months, had a range between elastic limits of from 82 000 to 98 000 lb. per sq. in., against a primitive elastic limit of 34 400 lb. per sq. in., as shown in Table 10.

After referring to the fact that in some cases raising the elastic limit by over-straining in tension reduces it in compression, Rosenhain states:

* "The Elastic Limits of Iron and Steel under Cyclical Variations of Stress", by Leonard Bairstow, *Phil. Trans.*, Royal Society, Vol. 210, p. 37.

† *Ibid*, p. 53.

"It is difficult to see how the formation of hard amorphous layers on surfaces of slip can account for a softening of the metal in relation to compression while producing hardening as against tension."* Mr. Prichard.

TABLE 10.—RE-TEST OF EYE-BAR STEEL.

Compiled from Watertown Arsenal Report, 1890, p. 731.

Original Eye-bar { Elastic Limit 34 400 lb. per sq. in. / Strained to 54 350 " " " "

Specimens from bar tested 3 years and 3 months later.

How specimens were taken.	UNANNEALED SPECIMENS. ELASTIC LIMIT PER SQUARE INCH.		ANNEALED SPECIMENS. ELASTIC LIMIT PER SQUARE INCH.	
	In tension.	In compression.	In tension.	In compression.
Crosswise.....	40 000	51 000	40 000	43 000
Diagonally.....	40 000	47 000	42 000	40 000
Lengthwise.....	63 000	35 000	47 000	42 000

It is not at all necessary to attribute paradoxical qualities to the "amorphous layers" to explain the softening of the metal in relation to compression which sometimes results from over-straining in tension, as it can be explained much better by the changes which occur in the balanced internal stresses whenever the metal is over-strained.

In 1848, James Thomson (the elder brother of Lord Kelvin), an engineer and eminent physicist, by a pure effort of scientific reasoning, and without any tests on the subject to guide him, deduced and published† the following theory:

"The considerations adduced seem to me to show clearly that there really exist *two elastic limits* for any material, between which the displacements or deflexions, or what may in general be termed the changes of form, must be confined, if we wish to avoid giving the material a set, or, in the case of variable strains, if we wish to avoid giving it a continuous succession of sets which would gradually bring about its destruction; that these two elastic limits are usually situated one on the one side and the other on the opposite side of the position which the material assumes when subject to no external strain, though they may be both on the same side of this position of relaxation; and that they may therefore with propriety be called the *superior* and the *inferior limit* of the change of form of the material for the particular arrangement which has been given to its particles; that these two limits are not *fixed* for any given material, but that, if the change of form be continued beyond either limit, two new limits will, by means of an alteration in the arrangement of the particles of the material, be given to it in place of those which it previously possessed."‡

‡ Encyclopædia Britannica, 9th Ed., Vol. VII, p. 800.

Mr. Prichard.

Thomson illustrated his theory by demonstrating theoretically, for a particular case of torsion, that a bar, originally free from initial internal stress, could have its elastic resistance to torsion increased one-third in the direction of the straining force, and decreased one-third in the opposite direction, by a certain degree of over-straining; and he pointed out that the same principles are applicable to beams subjected to transverse loading. He did not allude to direct tension and compression, but his theory can readily be extended to such cases. For illustration: if a pair of soft steel eye-bars, with an elastic limit of 30 000 lb. per sq. in., and a pair of hard steel eye-bars of the same size, with an elastic limit of 50 000 lb. per sq. in., are symmetrically coupled in the same link by pins, and supported laterally, they can be alternately strained in tension and compression to 30 000 lb. per sq. in. without exceeding their elastic limits, provided they are free from flaws and initial internal stresses and have perfect elasticity to the elastic limit; thus showing the range of the elastic field for the link between the superior and inferior limits of its elasticity to be 60 000 lb. per sq. in. If, however, the link is strained in tension to the point where the tension in the hard steel bars is just below their elastic limit, the tension in the soft bars will be very little above 30 000 lb. per sq. in., and in the link as a whole it will be about 40 000 lb. per sq. in.; and, after the link is relieved of its load, the soft bars will be strained to 30 000 minus 40 000, or 10 000 lb. per sq. in. in compression, and the hard bars to 50 000 minus 40 000, or 10 000 lb. per sq. in. in tension. A subsequent compressive load of 20 000 lb. per sq. in. applied to the link will then strain the soft bars to their elastic limit in compression of 30 000 lb. per sq. in.; or a subsequent tensile load of 40 000 lb. per sq. in., applied to the link, will then strain them to their elastic limit in tension of 30 000 lb. per sq. in., and the elastic field, as before, will be 60 000 lb. per sq. in. If the compressive load, instead of being 20 000 lb. per sq. in., were enough greater (10 000 lb. per sq. in. of link greater, or 20 000 lb. per sq. in. of hard bars, which must now carry all the additional load, the soft bars being the "lazy horse") to strain the hard bars to 30 000 lb. per sq. in., all the bars, hard and soft, would become entirely free from balanced internal stresses when the link was relieved of its load.

When the hard and soft metals, instead of being segregated in separate bars, are intimately mixed in each bar, the action is more complicated, but the principles which govern are the same.

According to Thomson's theory, initial internal stresses can be eliminated and the elastic field shifted at will by over-straining.

Thomson's theory takes no account of the mobile or viscous films of metal which result from over-straining,* nor of the hardening pro-

* Subsequent to the promulgation of Thomson's theory of over-straining, he wrote a paper, in 1861, on crystallization and liquefaction as influenced by stresses tending to change of forms in crystals.

duced by their resolidification. Instead, he based it in part on the tentative proposition: "That no change in the hardness of the substance composing the material has resulted from the sliding of its particles," after it has been strained beyond its elastic limit. Mr. Prichard.

The viscous films will solidify and cement the adjacent crystalline surfaces during a rest, whether the metal is free from stress or is stressed, or even while the stress is fluctuating, provided the fluctuations are not alternations.

Moderate over-straining followed by rest or by only moderate fluctuations tends to increase the elastic limit of the metal by liquification and resolidification in harder, stronger form of the weakest films or portions; that is, the portions having the lowest elastic limits, and this tends to increase the elastic field, as illustrated in Table 10.

Alternations of stress appear to be very fatiguing by hindering the resolidification of the viscous metal and by squeezing it from between the sliding crystalline surfaces, and thus producing permanent injury and weakness in the form of cracks.

Alternations of stress may actually take place when repeated stresses seem to be all of one kind; for instance, in the case of the link of soft and hard steel bars, previously analyzed, repeated loads from zero to 40 000 lb. per sq. in. would involve repeated alternations from 30 000 lb. per sq. in. tension to 10 000 lb. per sq. in. compression.

If at any time the stress fluctuates without rest and the fluctuations exceed twice the elastic limit of what is at that time the weakest portion of the metal, over-straining and stress reversals, the conditions which make for permanent fatigue, are bound to ensue, no matter how well the elastic field is adjusted to the conditions; and even when the range of fluctuations exceeds simply the elastic limit of the said weakest portion, over-straining and stress reversals are likely to ensue if the conditions as regards balanced internal stresses are sufficiently unfavorable.

Any piece of steel manufactured by hot-rolling or hot-forging is, to a greater or less extent, strained initially by balanced internal stresses, besides which it contains microscopic flaws which cause unequal distribution of stress from external forces; hence (assuming that its condition as regards balanced internal stresses has not been adapted by previous suitable over-straining and rest treatment to the particular stress conditions to which it is to be subjected) the range between the limits within which the loading can continuously fluctuate without producing both mobile metal and alternate stresses, must in practice for such a piece be less than twice the elastic limit of its weakest constituent metal. The elastic field of such a piece is naturally normal; that is, its yield point and the imperfections in elasticity within the yield point may naturally be expected to be about the same in tension as in compression; and the range of fluctuation, which will

Mr. Prichard.

not, at the start of a continuous series of stress fluctuations, produce more mobile metal than is consistent with subsequent endurance, will be greatest when the fluctuation is between equal tension and compression, less when the fluctuation is between zero and an upper limit of tension or compression, and least when the fluctuation is between two limits of the same kind of stress, one of which is the greatest possible.

Bauschinger, Unwin, Stanton, Bairstow, and others who have critically studied cycles of stress and compared the numbers of repetitions necessary to produce rupture at different stress intensities, have concluded, after plotting the curves of rupture, that these curves indicate certain limiting stress intensities, for different materials, below which rupture would not occur, no matter how often the cycles were repeated. Mr. Moore, however, does not accept the conclusions of these experimenters and analysts. Instead, he states:

"Professor Basquin, of Northwestern University, has pointed out that, for a considerable range of stress, the results of repeated stress tests of metals are well represented by an exponential equation."

The British experimenters, Eden, Rose, and Cunningham, and the American experimenters, Upton and Lewis, also pointed out such an apparent relation. Mr. Moore further states that, as a result of investigations on which he and Mr. F. B. Seely have been engaged:

"The following modification of Basquin's formula is proposed:

$$S = \frac{B}{(1 - Q)\, N^{0.125}}, \quad * \; * \; *$$

in which

S = fiber stress necessary to cause failure;
N = corresponding number of repetitions of stress (the 'life' of the piece);
Q = ratio of minimum stress applied to maximum stress ($Q = 0$ for load varying from zero to a maximum, $Q = -1.0$ for a completely reversed load);
B is an experimentally determined constant."

Mr. Moore has stated to the writer:

"This equation is proposed as a working formula, and is based on test results near the minimum for the test data available. Many individual tests, especially those made on rotating shaft specimens under bending, show higher results than are given by this formula."

According to this formula, any cycle of stress, if successively repeated, will eventually cause failure.

The Watertown Arsenal's endurance tests of shafts of open-hearth steel of various grades, as given in Table 3, by covering a much greater range of repetitions of cycles of stress than is usual in experiments of this kind, afford a good opportunity to try out Moore's formula and the opposite contentions of the other school of analysts cited. The

writer has accordingly diagrammed these tests. They all plot quite close to smooth curves, which, as far as they go, and they go far enough to be very assuring to structural engineers, support the contention that there are limits within which cycles of stress can be continuously repeated without resulting in failure (it should be remembered, however, that mechanical engineers have to do with repetitions of stress far outnumbering anything in these tests; for instance, the rotations of shafts of steam turbines in a few years amount to billions). One of these curves is shown in Fig. 14, together with the locus of Moore's formula, which, it will be observed, does not agree with the experi- Mr. Prichard.

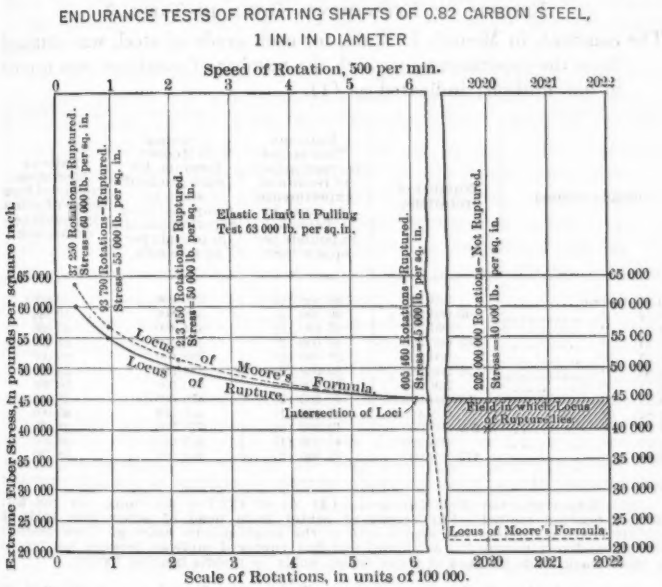

FIG. 14.

ments. Mr. Moore suggests, in a letter to the writer, "A lower value of exponent than 0.125 would give better agreement with these particular test results."

To make a further comparison of Moore's formula with the experiments in Table 3: first, the values of B were obtained for each grade of steel, by taking for each case the values of N and S from the test in which the number of rotation was closest to one million; second, by computing in each case from these values the value of S for the maximum number of rotations given in the table; third, by placing the

Mr. Prichard.

values of S, thus computed from Moore's formula, in juxtaposition with the values of S corresponding to the actual results of experiments. This comparison is given in Table 11.

From Table 11 it appears that the various grades of steel sustained, without failure from fatigue, millions of alternations of stress varying for the different grades from 49 to 87% in excess of the failure stress indicated by Moore's formula. The failure of the 0.34 carbon steel at 63 667 320 rotations was evidently due to wearing and scoring at the bearings, and not to fatigue.

TABLE 11.—COMPARISON OF MOORE'S FATIGUE FORMULA WITH RESULTS OF EXPERIMENTS GIVEN IN TABLE 3.

The constant, in Moore's formula, for each grade of steel, was obtained from the experiment in which the number of rotations was nearest to one million; indicated as (1).

Grade of steel.	Number of rotations.	Extreme fiber stress corresponding to results of experiments as given in Table 3, in pounds per square inch.	Constant in Moore's formula, for each grade of steel, as computed from experiments (1), in pounds per square inch.	Extreme fiber stress computed from Moore's formula, in pounds per square inch.
0.17 carbon.....	293 510	40 000 (1)	386 800	40 030
0.17 "	100 000 000	30 000 (2)	386 800	19 340

(1) Ruptured; (2) Not Ruptured; (3) At 63 432 700 rotations, bar run hot; middle bearing melted. Bar scored at center from head of screw that holds up middle bearing fixture; bar also scored at the south middle bearing. New bearings put in, and test resumed. At 63 667 320 bar ruptured midway between bearings at a score mark made by head of screw which holds up middle bearing fixture.

Some of the shafts recorded in Table 3, after being subjected to many millions of alternations of stress without rupture, as indicated in that table, appear to have had their capacity for endurance enhanced by the straining they had undergone, as they were subsequently subjected to endurance tests at higher loads, which they then sustained for more rotations than the shafts which had not been subjected to previous tests; for instance, the 0.17 carbon shaft, after resisting 100 000 000 rotations at a stress of 30 000 lb. per sq. in., stood 6 470 460 rotations at 35 000 lb. per sq. in. before rupture, against 5 757 920 rotations at 35 000 lb. per sq. in. of a shaft not previously tested; the 0.73 carbon shaft, after resisting 58 400 000 rotations at

40 000 lb. per sq. in. without rupture, stood 1 000 rotations at 45 000 plus 1 000 at 50 000 plus 1 000 at 55 000 plus 74 040 at 60 000 lb. per sq. in. before rupture, against 55 390 rotations at 60 000 lb. per sq. in. of a shaft not previously tested; the 1.09 carbon steel, after resisting 175 280 000 rotations at 35 000 lb. per sq. in. without rupture, stood 1 000 rotations at 40 000 plus 1 000 at 45 000 plus 1 000 at 50 000 plus 1 000 at 55 000 plus 17 350 rotations at 60 000 lb. per sq. in. before rupture, against 17 540 rotations at 60 000 lb. per sq. in. in a shaft not previously tested; an 0.82 carbon shaft, not listed in Table 3, after resisting 62 076 660 rotations at 35 000 lb. per sq. in. without rupture, stood 140 830 rotations at 55 000 lb. per sq. in. before rupture, against 93 790 rotations at 55 000 lb. per sq. in. of a shaft not previously tested. Mr. Prichard.

The only shaft which on re-testing did not on its face plainly show increased capacity for endurance as a result of the previous endurance test under moderate stress was the 0.55 carbon one. This shaft, after resisting 75 006 000 rotations at 30 000 lb. per sq. in. without rupture, was subsequently subjected once to 100 rotations and eight times to 1 000 rotations (8 100 in all) at 60 000 lb. per sq. in., with 1 334 060 rotations at 30 000 lb. per sq. in. interspersed between times, and then ruptured after 3 280 additional rotations at 30 000 lb. per sq. in. Against this, a shaft not previously tested resisted 12 490 rotations at 60 000 lb. per sq. in. before rupture.

Mr. Moore, to whom Table 11 was submitted in advance of publication, stated in reply:

"The divergence of test results from the proposed exponential formula is noted by Basquin, by Upton and Lewis, and by Moore and Seely. The advocates of an exponential formula for repeated stress calculations claim that the test data for numbers of repetitions of stress greater than ten million are very few, that while most test data for high values of N shows results above those given by exponential formulas, some data (Wöhler) seem in fair agreement with those formulas, and that in our present state of ignorance as to results of long-time repeated stress tests (which must continue for at least ten years longer, since the European war has caused the cessation of most, if not all, of the long-time tests now in progress) some formula which assumes that the same destructive action which occurs under high stresses will continue to act with diminished intensity under low stresses is a safer guide for the designer than is a fixed endurance limit, below which destructive action is assumed to cease. For structures the stresses given by the exponential formula and those given by the older endurance limits are about the same. For high-speed machinery the exponential formulas give lower stresses than do the old endurance limits.

"Messrs. Moore and Seely have attempted (in their paper before the 1915 meeting of the American Society for Testing Materials) to modify their proposed formula for certain cases by the addition of a 'probability factor' which is given as $(1 + 0.015\ N^{0.125})$. This factor

Mr. Prichard.

brings about a somewhat better agreement between the formula and results of most repeated stress tests in which N is greater than ten million. The proposed factor was purposely chosen to give conservative results."

The writer will not digress from the subject of his paper by including a discussion of the endurance of high-speed machinery parts, with their liability to accumulative vibration through synchronization of vibratory and loading periods, to centrifugal forces from unintentional and unapparent eccentricities in revolving masses, and to instability at critical or "whirling speeds", in addition to pulling, pushing, bending, and twisting loads; but, simply as a caution against snap judgments as to safety in proportioning such parts, he calls attention to the paradox that in some cases it is safer to use a shaft with a small diameter than a shaft with a large one. For instance, in a certain type of De Laval turbines the wheel with its shaft will revolve safely and smoothly at a tremendous speed (at a rate of 30 000 rev. per min. or 15 768 000 000 per year in the 5-h.p. turbines) about an axis which passes almost exactly through the actual center of the revolving mass, as distinguished from the nominal center, for the reason that the shaft being slender is flexible; whereas, if it were of much larger diameter, and correspondingly stiffer, there would be danger of intense bending stresses and of other detrimental phenomena from centrifugal force and vibration.

Professor Howe introduces the question of the effectiveness of raising the elastic limits of steel and iron by the cold-working of the material prior to putting it in service. There is no doubt that, when the cold-working strains are not too severe, the endurance to constant loads is increased. In this regard Thurston's endurance tests of wires, as given in Table 12, are pertinent. It is also very probable: first, that the material acquires a capacity for enduring stresses much higher than its primitive elastic limit before it was cold-worked, provided the range of variation in stress is kept somewhat less than the said primitive elastic limit; second, that, for occasional loads, with long intervals of rest between them, the range of variation in stress is much greater than the said primitive elastic limit. Looking at the question from a theoretical standpoint, it may also be, especially in the case of wire, that such a large proportion of the metal has been made viscous, and resolidified in much stronger form, that the elastic field will be enlarged, in some cases perhaps greatly enlarged, even for resistance to continuous cycles of stress. The question is one which can only be answered with any certainty by experience and by comparative endurance tests. Professor Howe cites some tests, but not enough to be conclusive, in his valuable and interesting article on the important question: "Are the effects of Simple Over-strain Monotropic?"* The

* *Proceedings*, Am. Soc. for Testing Materials, Vol. XIV, Part II (1914), p. 9.

Mr. Prichard.

writer does not know of many others, but presents in Table 13 a few, which are pertinent, on rotating shafts turned down from plain and twisted iron rods. It is not safe to draw conclusions from a few cases, but on their face the tests in Table 13 indicate: first, that the fourth turn of the rod strained the metal too severely; second, that the cold-twisting increased the length of the endurance to a given alternating stress. Whether or not the cold-twisting permanently increased the elastic field of resistance to continuous alternations of stress does not appear.

The enhancement of the elastic limit by cold-working affords an interesting field for experimental and theoretical investigation, and such investigation would be of much practical value to the mechanical engineer, and also, as regards wire cables, to the structural engineer. In general, however, the steel in which the structural engineer is interested is hot-rolled, hot-forged, or cast.

The stresses which are developed in structures vary in intensity, and, even when the loads are frequently applied, there are long intervals between the stresses of greatest intensity and between the greatest extremes of stress. It is the difference between the frequency of the recurrence of such extremes and the recurrence of the extremes in endurance tests that the writer had in mind in making the statement, on page 1456, quoted by Mr. Stanton. High stresses only slightly within the primitive yield point, repeated or even alternated at long intervals would probably do little injury beyond a slight permanent deformation to tension members and stiff compression members, provided the metal had not been previously weakened by a number of frequent repetitions of great variations in stress.

TABLE 12.—(THURSTON'S TABLE NO. 11)* ENDURANCE OF IRON UNDER DEAD LOADS.

Per cent. maximum static load.	TIME UNDER LOAD BEFORE FRACTURE.

None (natural state)..	20 000	1 000 000	Not ruptured.
	25 000	1 716 380	Ruptured.
		2 716 380	Total rotations.
2.....	25 000	3 032 130	Ruptured.
3.....	25 000	12 074 960	Ruptured.
4.....	25 000	7 043 080	Ruptured.

Mr. Stanton calls attention to a phenomenon recorded in Mr. Bairstow's valuable paper* on the range of the elastic limits, as follows:

"Experiments on an axle steel with a yield point of 24.9 tons per sq. in. showed that in repeated loadings from 0 to 23.2 tons per sq. in. no sign of want of elasticity occurred until after 6 000 loadings, when a permanent extension of the order of the yield took place."

That there should be a difference in yield points in different specimens of the same steel is not remarkable. That the difference in the cases referred to was due to the manner of developing the yield seems probable. As the ultimate tensile strength of the specimen of axle steel which developed the yield point of 24.9 tons was 38.2 tons, the ratio of yield point to ultimate was 65.1%, or, for a yield point of 23.2 tons, 60.7 per cent.

It is doubtful whether a primitive elastic limit much in excess of 60% of the ultimate is a direct criterion of the maximum load which can be continuously repeated from zero to a maximum without causing failure. In some cases of high ratios the change from nearly perfect elasticity to rapid yield is so sudden and pronounced as to suggest that a slight change in conditions would have caused the metal to yield under a considerably lower stress; for instance, a piece of steel tested at the Watertown Arsenal† for comparison of testing machines, at 40 000 lb. per sq. in., or 82.9% of its ultimate tensile strength, had no set in a gauged length of 8 in., and had a modulus of elasticity of 30 000 000; but, at 40 600 lb. per sq. in., it suddenly yielded, and the load fell to 30 000 lb. per sq. in., which is 62.2% of the ultimate tensile strength of 48 240 lb. per sq. in. This specimen had the greatest drop

* *Phil. Trans.*, Royal Society, Vol. 210, p. 35.
† Report for 1904, p. 197.

at the yield point which the writer has ever seen recorded. Ordinarily, the drop is within 10% of the load at the yield point. In general, the drop in load at the yield point is greatest for soft and medium steels with high elastic limits, and it decreases with decrease in the ratio of elastic limit to ultimate and with increase in ultimate. Mr. Prichard.

For structural purposes, a pronounced yield is failure, and its careful observation in tests is of value accordingly. Low elastic limits which mark the beginning of a general yield are critical, but low elastic limits which are not followed within a few thousand pounds by a critical deformation are not very detrimental to tension members and stiff compression members, as their elasticity can be perfected by straining in service at the expense of a little permanent set. Such low elastic limits are caused, as explained by Mr. Howard, by initial internal stresses. The effect of such stresses on compression members, as also explained by Mr. Howard, is nearly akin to eccentricity. In other words, these stresses cause a deflection in compression members where, under ideal conditions, there would be none. This is one of the elements of weakness for which suitable provision is or should be made by use of some reasonable column formula.

Mr. Lynch does not present any data regarding the deformation which followed the "true elastic limit of 15 000 lb. per sq. in. or less" (which he states that plates with a tensile strength of more than 60 000 lb. per sq. in. often have), nor any other information from which to judge whether this "true elastic limit", as determined by the extensometer, was the real elastic limit of the steel, or simply the elastic limit of the piece in whatever condition as regards initial internal stresses it happened to be; which latter, owing to the initial internal stresses, may be much less, as Mr. Howard has pointed out. Eccentricity in loading in the testing machine, as Mr. Howard has also pointed out, and the non-observance of the practice of allowing "test pieces to 'rest' for a day or two before pulling", as pointed out by Mr. Speller, may likewise result in extensometer readings which are below the "real elastic limit" of the material.

Mr. McCulloch has cited eye-bars for which the micrometers indicated permanent sets under pulling loads of 5 000 lb. per sq. in.; and the writer could cite many other cases, but he does not know of any case in which the test showed that the steel of which the piece tested was composed had a real elastic limit as low as "15 000 lb. per sq. in.", nor of any case in which a piece of steel tested under repeated (not alternated) loads failed under a load of less than 35 000 lb. per sq. in., except one bar (which had unfilleted re-entrant angles where reduced in section and, therefore, was not a criterion) tested by Wöhler to failure on the 274 969th repetition of a load of 31 100 lb. per sq. in. Tests of steel and iron to failure under thousands and millions of repetitions of simple tension were made by Wöhler, as given in Table

Mr. Prichard.

14, and by Bauschinger, as given in Table 15. The writer does not know of any others.

There is some difference between Mr. Lynch's claim that "Plates having a tensile strength of more than 60 000 lb. per sq. in. may, and often do, have a true elastic limit of 15 000 lb. per sq. in. or less" and Dr. Waddell's statement that "The elastic limit for medium bridge steel is 35 000 lb. per sq. in." It is hardly likely that Dr. Waddell wishes to have this general statement taken too literally and without allowance for the differences which may be caused by variation in reduction in rolling and in the temperature at which the steel is rolled, as he has previously published* the yield points indicated in tests made at the Drexel Institute from the same heat of ordinary open-hearth carbon steel, as follows:

12-IN. UNIVERSAL PLATES—HEAT NO. 33 342.

		Section, in inches.	Pounds per square inch.	Percentage of ultimate.
Average of	4 specimens,	1.510 by 0.355	38 800	60.5
" "	4 "	1.510 " 0.475	36 880	57.8
" "	4 "	1.510 " 0.755	33 420	53.8
" "	6 "	1.250 " 1.000	27 380	44.9
" "	2 "	1.250 " 0.995	25 700	43.8

The yield points were indicated by a set of 0.01 in. in 8 in., and were a little lower than indicated by the drop of the beam.

Dr. Waddell had occasion to investigate extensively the subject of the elastic limit, as appears in the valuable paper in which the Drexel Institute tests above cited were published; but there are many engineers who are not familiar with the extent of the differences in reduction in cross-section and in the temperature at which reduced, incident to the manufacture of structural steel (with its wide range of shapes and sizes), and who do not realize the effects on the elastic limit of the reduction and of the temperature at which the reduction is made. In this regard, interesting tests were made at the Watertown Arsenal of bars from an open-hearth steel ingot, forged down to different degrees and at different temperatures, as given in Table 16.

The writer fully appreciates the worth of the previous efforts of Dr. Waddell, Mr. Molitor, and other eminent engineers in combating the application to bridge design of Launhardt's and similar fatigue formulas. Largely through their efforts, such use of these formulas has declined, but, unfortunately, has not ceased. It is noteworthy, however, that in this discussion the application of such formulas to bridge design has not had a single champion.

The bars marked *A* had well-rounded corners at the point where the small middle part of the test bar joined the enlarged end. Those marked *B* had square corners.

Three equivalents, in pounds per square inch, have been given by different authorities for the centner zoll: namely; 97.24, 104 and 107, accordingly as they used the old German or assumed the old Prussian or the present German value for the centner. The old German centner was 100 lb. (Century Dictionary); the old Prussian pound was 467.7 grams (Johnson's and Brockhaus' Encyclopædias); the old Prussian zoll was 1.03 English inches (Webster's Dictionary), which brings 97.24 lb. per sq. in. as the equivalent of the centner zoll; this value was used in computing the above.

"According to Bauschinger (Meth. aus Mech.-Tech. Lab. in München, Heft 13, p. 36, 1886) the centner per zoll in which Wöhler gives his results is equivalent to 6.837 kilos per square cm." or 97.24 lb. per sq. in. (Encyclopædia Britannica, 9th Edition, Vol. XXII, p. 601).

Mr. Prichard.

The writer, as his previous papers* show, is in full sympathy with Mr. Molitor's efforts to secure reasonable safety for bridges when overloaded.

In conclusion, the writer emphasizes the facts: that strength which can only be acquired at the expense of undue deformation is of little value; that original faults in elasticity which can be corrected in service without undue deformation are not critical; that the real strength of any member of a structure is measured by the loads it can

Mr. Prichard.

sustain without undue deformation under the conditions of service during the lifetime of the structure, as determined by other causes; that, in judging the real strength of structural members from tests, a knowledge of the principles of physical metallurgy is very useful; and that, in consideration of the conditions of manufacture, considerable variation in the strength of such members, even when made of steel from the same melt, should be expected.

Paper No. 1371

A REVIEW OF THE REPORT OF CAPTAIN ANDREW TALCOTT CHIEF ENGINEER MEXICO AND PACIFIC RAILROAD EASTERN DIVISION FROM VERA CRUZ TO MEXICO EXPLORATIONS SURVEYS ESTIMATES 1858

By Emile Low, M. Am. Soc. C. E.

With Discussion by Messrs. T. K. Mathewson, H. T. Douglas, W. T. Ingram, L. Perez Castro, T. M. R. Talcott, H. M. Taylor, and Emile Low.

Synopsis.

The object of this paper is to record the achievements of an American engineer in railroad building in a foreign country under crucial conditions, to render him proper recognition, and to pay the tribute due him.

The first railroad built in Mexico was what is now called the Mexican Railway, extending from Vera Cruz to the City of Mexico, a distance of 264 miles. Barring the two short stretches at each terminus, built prior to 1858, this railroad was constructed during the period 1861-72. The construction was intermittent, having been interrupted at times by civil strife and again on account of financial difficulties.

Under the auspices of the President of the Mexican Republic, imposing ceremonies commemorating the completion of this railway were held in the City of Mexico, on January 1st, 1873, on which date it was officially opened for traffic. Between Orizaba and Boca del Monte

occurs the famous Maltrata Incline, which, as an engineering achievement, is without parallel in railroad construction. This section, together with other portions of the railroad, is an everlasting monument to the ability of Capt. Andrew Talcott, an eminent American civil engineer, who located the railroad and also constructed the major portion of the line.

Before giving a short biography of Capt. Talcott, attention is invited to extracts from the books of two well-known authors who visited Mexico and whose descriptions of this wonderful section of railroad find a responsive chord in the breast of every one who has passed over it.

"A little valley lies spread before us now, an emerald embosomed in the mountains, called *La Joya,* the Jewel, in the center of which is the station of Maltrata.

"Beyond this the track literally *climbs* the mountain, approaching it by great curves. All the way up the hills you can trace the road, its serpentine trail drawn in and out the valley and along the ridges, ever and anon doubling upon itself, but ever climbing. Beyond a water tank is a narrow bridge, ninety feet long, and spanning a chasm that ends only at the valley below, two thousand feet downward.

"Glorious are the views of Maltrata obtained as the train crawls in and out of the cuts. In the last thirteen miles we have climbed over three thousand perpendicular feet."*

"But our way lies onward towards the mountains. A wildness of landscape, unpictured before, opens to the view. Here rise weird rock forms, Nature's cathedral towers and grim façades, magnificent in solitude, and awe inspiring.

"Still onward and upward lies the way. One of the most remarkable railways in the world ascends to gain this steep zone, and serpentines among sheer descents to gain the summits of abrupt escarpments, from which (a remarkable feature of the topography of the eastern slope of Mexico) the traveler looks down as into another country and climate, upon those tropical valleys which he has left below. This is the Mexican Vera Cruz railway."†

Capt. Talcott was born in Connecticut, on April 20th, 1797. He entered the West Point Military Academy on April 9th, 1815, and was graduated and promoted in the United States Army to Brevet Second Lieutenant, Corps of Engineers, on July 24th, 1818, and to Captain. on December 22d. 1830. He resigned his commission in

* "Travels in Mexico", by F. A. Ober, 1884.
† "Mexico", by C. Reginald Enock, 1909.

the Army on September 21st, 1836. During this time, he had had charge of many engineering projects, and supervised the construction of important fortifications, among which were the defences at Hampton Roads, Va., Fort Adams, R. I., Fort Delaware, and Fort Monroe, serving on the last named as Superintending Engineer of Construction, from July 20th, 1828, to July 31st, 1834.

He was also the author of the "Talcott Method" of determining latitude, of which practical use was first made by him as Astronomer in the determination of the boundary line between the States of Ohio and Michigan, in 1832-36.

During his civil life, among many other engagements were those of Adjunct Chief Engineer, New York and Erie Railroad; Chief Engineer, Richmond and Danville Railroad, 1848-55; Chief Engineer, Eastern Division, Ohio and Mississippi Railroad, resigning from the latter to become Chief Engineer of the Mexico and Pacific Railroad, on December 1st, 1857, at a time of life when most men think seriously of retiring from active duties. After the presentation of his report in April, 1859, Capt. Talcott was otherwise engaged, but resumed his connection with this railroad early in 1862, resigning his position on February 10th, 1867, when the nearly completed work was suspended at the time of the withdrawal of the French Army from Mexico.

He died on April 22d, 1883, in Richmond, Va., being at the time the oldest graduate of the West Point Military Academy.

The paper is divided into eight parts, as follows, and, for a clearer understanding, the main reports are given verbatim, in order that there may be no perversion of facts:

1.—Introduction.
2.—Historical.
3.—Physiography.
4.—Explorations and Surveys.
5.—Report of Capt. Andrew Talcott.
6.—Summaries of Special Reports, *A, B, C, D, E,* and *F.*
7.—Maps, Profiles, Plans, and Estimates.
8.—Appendices *A, B, C, D, E,* and *F.*

It is opportune to state here that the original records used in the compilation of this review are now the property of Col. T. M. R. Talcott, of Richmond, Va., one of the two living sons of Capt. Talcott,

and a former member of the American Society of Civil Engineers, who kindly furnished the data for publication. Other data were obtained from various sources.

1.—Introduction.

In all civilized countries, before the advent of railroads, highways of more or less elaborate construction formed the means of communication. Mexico was no exception to this rule. Two highways, by divergent routes, connected Vera Cruz, the seaport of Mexico, with the City of Mexico, the capital of the country. One of these highways, known as the northern, passed to the north of the mountain, Cofre de Perote (12 500 ft. high), and the other, the southern, to the south of the mountain, Pico de Orizaba (17 873 ft. high). A straight line drawn from Vera Cruz to the City of Mexico passes about midway between these extinct volcanoes, the air-line distance being about 200 miles.

The peaks of the volcanoes are about 30 miles apart and are connected by a ridge, the lowest elevation of which above sea level is about 10 000 ft. Puebla was and is now the largest city between the coast and the capital. Both highways passed through this city, or it might be more properly said, they joined here, there being only one main highway between Puebla and the City of Mexico.

North of Puebla is the mountain of Malinche, an isolated peak rising 6 000 ft. above the surrounding plain. A branch of the northern highway passes to the north of this extinct volcano, through Huamantla, joining the lesser Puebla-City of Mexico *camino real* west of Apizaco. The main city on the northern highway is Jalapa and that on the southern, Orizaba. Still farther west are the well-known volcanoes, Popocatepetl and Ixtaccihuatl, the slopes of the latter extending some miles to the north. These mountains fixed absolutely the routes of travel, first the trails used by the native Indians, next the highways built by Cortez and his followers, and finally the location and construction of railroad lines.

The highways were built about 1800 by the consulates of Vera Cruz and Mexico. Later, the one through Jalapa was virtually abandoned, mainly on account of the larger number of important towns along the southern highway. Although there was no appreciable difference in length, it took 4 days to make the journey by diligence

from Vera Cruz to the City of Mexico *via* Jalapa, and only 3 days *via* Orizaba.

These roads, notwithstanding their dilapidation due to gradual neglect, were originally admirable specimens of solid construction, as were also the bridges on them, the Puente Nacional on the Jalapa Section deserving special mention.

2.—Historical.

On August 31st, 1837, under the administration of Gen. Anastacio Bustamante (who was President from 1837 to 1839), Don Francisco Arrillaga, a merchant of Vera Cruz, obtained an exclusive privilege for the construction of a railway from the City of Mexico to Vera Cruz, with a branch to Puebla. The proposed line had one great drawback, namely, that it only united Vera Cruz, Puebla, and the City of Mexico, leaving Cordoba and Orizaba isolated on one side, and Jalapa on the other.

The projector estimated the cost of the main line at $5 000 000 and that of the Puebla Branch, leaving at Apizaco, at $500 000. After some surveys had been made, the concession was forfeited, no construction work having been done.

A new concession was granted on May 31st, 1842, by President Don Antonio Lopez de Santa Ana, for the construction of a railroad from Vera Cruz to the Rio de San Juan, in the State of Vera Cruz, about 20 miles west. A tax formerly known as *de averia* (highway repairs) was re-established, and the proceeds were applied to railroad building and to repairs of the Jalapa Highway. During the 7 years of this grant, the company holding it constructed only 1 league of railroad and then abandoned the concession, the Government confiscating the works and prosecuting them until 1854, when a tramway had been built to La Caleta (a suburb of Vera Cruz) and the railroad was extended to the San Juan River.

On August 2d, 1855, Messrs. Mosso obtained a charter to construct a railroad from San Juan (near Vera Cruz) to Acapulco, virtually from the Atlantic to the Pacific. The resulting operations were the construction of a short stretch of railroad about 3½ miles long from the City of Mexico to the neighboring village of Guadalupe Hidalgo, which was opened for traffic on January 11th, 1857. This short line and the somewhat longer one out of Vera Cruz to Tejeria comprised

at this date the entire railway system of Mexico, some 20 miles, much of which was built under the direction of the late Robert B. Gorsuch, Hon. M. Am. Soc. C. E., later an Assistant under Capt. Talcott.

The Mosso concession was sold to Don Antonio Escandon, who, on August 31st, 1857, obtained from the Mexican Government the right to construct a railroad from Vera Cruz to the Pacific Ocean. Señor Escandon also bought from the Government the line between Vera Cruz and San Juan, near Tejeria. Previous to this date all attempts to connect Vera Cruz with the City of Mexico by rail were abortive, and it may be said that the realization of what ranks as a great engineering enterprise began at that time.

The dominant spirit in this great undertaking was Don Manuel Escandon, who placed his younger brother, Antonio, at the head of it, because he realized (as actually happened) that he himself would probably not live long enough to carry an enterprise of such magnitude through to completion. The death of Don Manuel Escandon occurred in the City of Mexico, on June 7th, 1862.

3.—Physiography.

The surface features of Mexico consist of an immense elevated plateau, with a chain of mountains on its eastern and western margins, which extend from the United States frontier southward to the Isthmus of Tehuantepec; a fringe of lowlands (*tierras calientes*) between the plateau and the coast on each side; a detached, roughly mountainous section in the southwest, which belongs to the Central American Plateau; and a low sandy plain covering the greater part of the Isthmus of Yucatan. The Peninsula of Lower California is traversed from north to south by a chain of barren mountains which cover the greater part of its surface. The slopes are precipitous on the east coast, but, on the west, they break down in hills and terraces to the Pacific. This range may be considered to be a southward continuation of the California Sierra Nevada.

The Great Plateau of Mexico is very largely of volcanic origin. Its superstructure consists of igneous rocks of all descriptions with which the original valleys between its marginal ranges have been filled by volcanic action. The remains of transverse and other ranges are to be seen in the isolated ridges and peaks which rise above the

level of the table-land, in some cases forming well-defined basins; otherwise, the surface is singularly uniform in character and level. The two noteworthy depressions in its surface, the Valley of Mexico and Bolson de Mapimi, once contained large bodies of water, of which only small lakes and marshy lagoons now remain.

The highest part of this great plateau is to be found in the States of Mexico and Puebla, where the general elevation is about 8 000 ft. Southward, the slope is broken into small basins and terraces by transverse ranges, and is comparatively abrupt. Northward, the slope is gentle, and is broken by several transverse ridges. At Ciudad Juarez (adjoining El Paso, Tex.), on the northern frontier, the elevation is 3 600 ft., which shows a slope of only 4½ ft. to the mile.

The mountain ranges which form part of the great Mexican Plateau consist of two marginal chains known as the Sierra Madre Occidental, on the west, the Sierra Madre Oriental, on the east, and a broken, weakly-defined chain of transverse ranges and ridges between the Eighteenth and Twentieth Parallels, known as the Cordillera de Anahuac. The Sierra Madre Oriental consists of a broken chain of ranges extending along the eastern margin of the plateau from the great bend in the Rio Grande southeastward to about the Nineteenth Parallel. In the north these ranges are low, and offer no great impediment to railroad building; south of Tampico, however, they are concentrated in a single lofty range. This range extends southeastward along the western frontier of the State of Vera Cruz and includes the snow-capped cone of Orizaba, or Citlaltepetl (18 209 ft.), and the Cofre de Perote, or Nanchampopetl (13 419 ft.). The eastern slopes are abrupt and difficult, and form a serious impediment to communication with the coast. Rising from the open plateau half way between this range and the City of Mexico is the isolated cone of Malinche, or Malintzin (14 636 ft.). Some 20 miles southeast of the City of Mexico are the gigantic snow-clad volcanoes of Popocatepetl (Smoking Mountain) and Ixtaccihuatl (White Woman), 17 888 and 17 343 ft., respectively.

The lowland or *tierra caliente* region, which lies between the Sierras and the coast on both sides of Mexico, consists of a sandy zone of varying width along the shore line, which is practically a tide-water plain broken by inland channels and lagoons, and a higher belt of land,

rising to an elevation of about 3 000 ft., formed in great part by the débris from the neighboring mountain slopes.

The peculiar surface formation of Mexico, a high plateau shut in by mountain barriers with a narrow lowland region between it and the coast, does not permit of the development of large river basins. The hydrography of Mexico, therefore, is of the simplest description, a number of small streams flowing from the plateau or mountain slopes eastward to the Gulf of Mexico and westward to the Pacific.

4.—Explorations and Surveys.

On December 2d, 1857, Don Antonio Escandon, in consultation with Gen. Manuel Robles, who represented the Mexican Government at Washington, engaged the services of Andrew Talcott, former Captain in the Corps of Engineers, United States Army, to make surveys for a railroad from Vera Cruz to the City of Mexico.

Immediately after his appointment Capt. Talcott organized a corps of engineers, in the City of New York, which sailed from New Orleans, La., on January 1st, 1858, and landed in Vera Cruz on January 4th. The members of this corps were: Capt. Andrew Talcott, Chief Engineer; Andrew B. Gray, Quartermaster and Commissary; J. S. Stoddart, Richard Page, and L. Van Wyck, Assistant Engineers.

First Brigade.—M. E. Lyons, Chief Engineer; E. M. Richards, R. F. Stack, T. W. Sargent, W. W. Dechert, A. C. Hall, E. McLenegan, J. Radnich, James J. Arnold, and George E. Clymer.

Second Brigade.—R. B. Gorsuch, Chief Engineer; D. S. Crosby, W. R. Eastman, A. Van Burcke, James Emmet, T. A. Emmet, H. G. Webber, L. B. Ward, O. W. Boynton, Alfred Delano, and D. M. Gorsuch.

Exploring Party.—Sidney Coolidge, Chief; T. M. R. Talcott, Charles Miller, C. A. Wolf, and George R. Talcott.

Of the foregoing, Messrs. T. M. R. Talcott (son), of Richmond, Va., and W. R. Eastman, of Albany, N. Y., are still living.

On his arrival Capt. Talcott found the country in a state of turmoil; for 3 years Mexico was a prey to civil war between two rival governments, the Republicans at Vera Cruz under Juarez, and the Reactionaries at the Capital.

With a view to an examination of the two principal routes from Vera Cruz to the table-land, one *via* Orizaba, and the other *via* Jalapa, two brigades of engineers had been organized before leaving the United States, as previously indicated.

Viewed from the ocean side, in the State of Vera Cruz, the almost perpendicular rocky walls, rising to a height of 10 000 ft. and more above ocean level, seemed to preclude the possibility of constructing a railroad from the lowlands to the plateau, but this was the problem which confronted Capt. Talcott and which he was called on to solve.

Comparative quiet having set in, the surveys of these two routes progressed favorably until the Constitutional President, Benito Juarez, who had escaped by the Pacific Coast, arrived at Vera Cruz, and military operations became more general, with the inevitable *pronunciamientos* which unsettled conditions wherever they occurred and made it difficult for the engineering parties to secure proper passports from recognized authorities to enable them to carry on their work without interruption and accomplish it at reasonable cost.

The cost of the surveys was being paid by Don Manuel Escandon, and they would not have been undertaken at this time if he had foreseen the breaking out of a revolution; but he was not willing to abandon them until it was determined that it was practicable to build a railway from Vera Cruz to the City of Mexico, and ascertain approximately what it would cost.

For these reasons, it was decided to reduce the force of engineers, and as the line *via* Orizaba was more advanced and conditions were less threatening on that route, it was deemed best to discontinue the survey *via* Jalapa until some future time, and concentrate the engineering force which was retained, in order to complete the survey of the Orizaba route as quickly as possible.

Previous to the arrival of Capt. Talcott, the Jalapa route had been examined by Don Pascual Almazan, a Mexican engineer. Subsequently, this route was examined (reconnoissance) by one of Capt. Talcott's assistants, Mr. E. M. Richards, whose report was unfavorable.

The Orizaba route was preferred, first, because it passed through towns of greater importance and a more cultivated and productive country; and second, because, notwithstanding the fact that it required great and difficult works, the line presented greater facilities than that by Jalapa, where the large number of ravines and the harder

nature of the soil would have required a much heavier outlay, without meeting the resources offered by the Orizaba route.

By the terms of the concession granted to Señor Escandon by the Mexican Government, surveys for two routes were required, one carrying the main line through Puebla, the other connecting Puebla with the main line by a branch. This was accomplished in the first case by running a line from the Maltrata Pass to Puebla, and thence to Apizaco in the Llanos de Apam, and, in the second case, by running a northerly line from the same point direct to Apizaco, the surveyed line from Puebla to Apizaco thus serving either as a part of the main line or as a branch line, as would be decided later.

On the completion of the surveys, in October, 1858, the engineers returned to the United States, and, under date of March 7th, 1859, Capt. Talcott forwarded to Señor Don Antonio Escandon his report "of the cost of constructing, maintaining, and operating a railway from Vera Cruz to the City of Mexico."

The receipt of this report was acknowledged by Señor Don Antonio Escandon from Mexico, under date of April 18th, 1859, and the report was also referred to in a letter from Tucabaya, dated May 19th, 1859, by Señor Don Manuel Escandon, a brother. In the former, Señor Escandon said:

"I consider it as a positive fatality that the unfortunate state of Mexico, with the civil war which now exists, prevents me for the moment from continuing the prosecution of a work which would most certainly become the solution of the real peace and prosperity of my country."

The report, as submitted by Capt. Talcott, is as follows.

5.—Report of Captain Andrew Talcott.

"Sr. Don Antonio Escandon,

"President of the M. & P. R. R. Co.

"Sir: On the 4th December, 1857, you engaged my services as Chief Engineer of your railway enterprise. It was at that time stipulated and agreed that the surveys between the port of Vera Cruz and the City of Mexico should be prosecuted vigorously and with a view to such a development of the topography of the country as would enable you to select the route of your proposed railway, define the same by maps, profiles, and specifications, and submit them to the Supreme Government for approval on or before the 31st of April following. This was one of the conditions set forth in the Decree of 31st of

August, 1857, granting you the exclusive privilege of connecting by a railway, the Capital of the Republic with the commercial emporiums of the Gulf and Pacific Coasts, Vera Cruz and Acapulco, or any other port, that might be deemed more eligible for the rapidly increasing commerce of the Pacific Coast.

"The time allowed was short, for the labor to be performed, *viz.*, to organize and equip a suitable Corps of Engineers, transport them to Vera Cruz, and thence with their instruments and camp equipage to the mountain passes, develop the most practicable of them, and from it to extend the surveys to Vera Cruz, and to the Capital, by lines of more than 260 miles in extent, and partly over ground exceedingly difficult and covered with the thick undergrowth, verdure, and vines of the tropics.

"A Corps of Engineers fully equipped and prepared for the service was landed at Vera Cruz on the 4th of January, but in consequence of the robbery and loss of the mail by the preceding packet from the United States, no arrangements had been made there for the transportation of the Corps; its movements were therefore so much delayed that over four weeks had elapsed before the Engineers were fairly at work surveying and exploring the mountain passes. During this interval a revolution had been in progress, and had resulted in the overthrow of the Constitutional Government at the Capital. It was the opinion of the best informed in Mexico that the struggle for power between the two contending parties would not soon be terminated by the triumph of either, and that the surveys could not be vigorously and successfully prosecuted during the then existing state of affairs. The obligation was no longer in force requiring the route to be defined and specifications filed before the 1st of May, as that had been suspended by the 26th Article of the Decree providing for such a contingency as had actually occurred. As only a small Corps could be advantageously employed for any length of time, whilst the Civil War lasted, a large reduction of the Corps was decided upon and effected, so that two-thirds left the country by the packet which sailed on the 7th of March from Vera Cruz.

"One important fact had however been ascertained, by the explorations and surveys previous to the reduction of the Corps, enough had been done to demonstrate that a railway could be constructed from Vera Cruz to the table-lands on grades and curves, susceptible of being worked by locomotive power, economically, and that the cost of such road would not be excessive. The survey had been confined to the route *via* Orizaba, but reconnoissances however had been made *via* Perote by Mr. Almazan, previous to the arrival of the Corps, and afterward verified by one of the assistants, Mr. Richards, whose reports were not favorable to the Northern route, but it had not been decided that a railway was impracticable; that the surveys were not made

with the same minuteness by the Actopan Valley, was partly from the want of time, to which may be added the civil strife which was waging in that section from March until the Corps left the Republic in October; but for the above mentioned causes this route would have been surveyed with sufficient minuteness to make a comparison of it with that *via* Orizaba. The examinations made were, however, sufficient to show that it is greatly inferior to the Orizaba route, though not minute enough to allow comparisons to be made of length, grades, curves, and cost of construction.

"It has been stated that a road by Orizaba can be economically worked by locomotive power, nevertheless it will be a road of high grades. The route surveyed reaches the table-land by a line of 111 miles, and attains at that point an elevation of 8 101 English feet, 4 000 of which must be overcome west of Orizaba, and where the summit is, in a right line, distant less than 16 miles.

"The face of the country is, however, favorable for developing and by the survey the distance exceeds 28 miles, and can be increased several miles if desirable. The question therefore arises: Is it desirable for the purpose of reducing grade to further develop the road? This is strictly a question of economy, and can be solved with much certainty. The locomotive and train must ascend the 4 000 ft., the line may be lengthened, and the cost of construction thereby increased, and an additional weight of train would be the consequence. There is a point, however, where the cost of working the road would be a minimum, this could be fixed with perfect precision, if the adhesion of the engine to the rail was constant, but it is not so, sometimes it is as low as 14% of the insistent weight, and it goes as high as 30 per cent. The grade most economical, so far as working power is concerned, changes as the adhesion changes. When the adhesion equals 30% a grade of $2\frac{9}{10}$ ft. per hundred would be worked with the least expense of power, at 20% $2\frac{3}{10}$ ft. per hundred; and 14% $1\frac{9}{10}$ ft. per hundred. These are the grades for up traffic only. Should the grade be increased to $4\frac{6}{10}$ ft. per hundred, the cost of power would only be increased $7\frac{2}{10}$%, with the adhesion of $\frac{1}{5}$th or 20 per cent. As the adhesion diminishes, the cost of working increases. (See Note *A*.)

"Thus far we have considered the expenses of but one item of railway transportation, that of power. The maintenance of way is another item generally as large on ordinary roads as the cost of power. Every mile added to lessen the grade increases the cost of keeping the road in repair, and the time required to travel over it. The greatest economy lies therefore in grades exceeding those that require the minimum power, even if the cost of construction be not thereby diminished, but under ordinary circumstances with higher grades the line would be shorter, and the reduction of cost greater in proportion, than the reduction of length. If a mountain line be 10 miles long,

with grades of 4 ft. in a hundred, it is probable that with grades of $4\frac{6}{10}$ ft. in a hundred, there will be a reduction of at least 10% in the length and more than that in the cost. The saving of the cost of this mile, and of the keeping of it in repair, will fully compensate for the additional power required for working the increased declivity. But the minimum cost of constructing, maintenance, and workings will depend on the amount of traffic, as well as the cost of power and maintenance, and from my investigations it appears that the most economical grade will not vary much from $4\frac{6}{10}$ ft. in the hundred, and this may be safely assumed as the maximum grade of the mountain road above Orizaba. The location which has been made with a ruling grade of 4 ft. in a hundred may therefore be revised, and a considerable saving thereby made, and curves of 400 ft. radii substituted for those of 350 ft., which in the experimental location were admitted on the mountain line. In all other portions the curvature is unobjectionable.

"By the terms of the grant, Vera Cruz, situated on the Gulf of Mexico in Latitude 19° 11′ 52″, was to be the eastern terminus of the railway. From this city a railway had already been constructed for about 14 miles, the title to which having been transferred to you, it was a matter of some importance to include as much of this road in your proposed line as could be advantageously used. It was found that about 9 miles could be used by the route *via* Orizaba, and an experimental location was made from this point to Cordoba, a distance of 25 leagues from Vera Cruz.

"This was as far as it was expected to extend the surveys at the time the Corps of Engineers was reduced in March, but this part of the country having become in a measure tranquil, and the labors of the Engineers uninterrupted, the experimental lines were continued up the country to the summit of Maltrata Pass and thence by Cuesta Blanca and Acacingo to Puebla, and by the Plains of Apam to Mexico. A second line was also run, branching from the first near the summit, and passing by a more northern route near Nopalucan and Huamantla, and intersecting the first line again some distance northwest of Tlaxcala. All these lines have been mapped and profiled, and made the basis of an approximate estimate of cost of the railway from Vera Cruz to the City of Mexico. It should be borne in mind that these are first experimental lines, and have not been perfected or revised into an 'Experimental Location' but still they afford very good data for an approximate estimate. It cannot be doubted that in many places ground better adapted may be found, and this is most especially the case going from Puebla to the Plains of Apam. In some places the cost may be considerably reduced, or better grades secured at the same cost. Grades have been laid down on the profiles of all the surveyed lines, and the quantities of excavation and embankment required to form a roadbed 16 ft. wide, with suitable slopes, have been carefully

calculated and entered upon the profiles, from which tables of quantities have been compiled which will be found appended hereto (marked 1).

"It appears from these surveys, that a railway *via* Puebla to the City of Mexico is $22\frac{8}{10}$ miles longer, than *via* Nopalucan, and the cost will be much greater; but Puebla is a city of too much importance to be excluded from such an enterprise, and must be served by a branch, if the more northern route is adopted. Which of the two projects should have the preference involves numerous considerations, and one very important one is the amount of direct traffic between Vera Cruz and Mexico. The greater it is, the stronger will be the objection to transporting it *via* Puebla, which not only increases the distance of carriage, but descends into the Palmar Valley 1 002 ft., to be again carried up to the northern line 824 ft.

"There are, however, many considerations to be urged in favor of the route *via* Puebla, as the trunk line, but it is not necessary to decide on the route at present, and better light may be hereafter obtained to guide your decision.

"By Puebla your road will be $289\frac{2}{10}$ miles in length, by the northern line $266\frac{4}{10}$ miles, and as a branch to Puebla will be $29\frac{6}{10}$ miles, it will require 296 miles of road, or $6\frac{8}{10}$ miles more than by Puebla.

"The cost of completing the several lines is exhibited in the following table:

"TABLE 1.—ESTIMATE OF THE COST OF COMPLETING A RAILWAY FROM VERA CRUZ *via* ORIZABA, AND PUEBLA, TO THE CITY OF MEXICO.

" Locality.	Length of line, in miles.	Roadway.	Track.	Structures.	Totals.
Vera Cruz to Cordoba	67.8	$1 625 000	$882 000	$169 000	$2 676 000
Cordoba to Orizaba	16.3	949 000	252 000	87 000	1 288 000
Orizaba to Maltrata Summit	28.1	1 392 000	420 000	18 000	1 830 000
Maltrata Summit to Puebla	60.2	681 000	903 000	74 000	1 758 000
Puebla to Junction	29.6	599 000	448 000	18 000	1 065 000
Junction to Mexico	87.1	358 000	1 232 000	219 000	1 809 000
Totals	289.1	$5 604 000	*$4 137 000	*$585 000	$10 426 000

Total cost of roadway	$10 426 000
Total cost of equipment	*1 260 000
Amount already expended on San Juan and Guadalupe Railways and on surveys	1 400 000
Total for roadway and equipment	13 086 000
No data for estimating { General management, real estate, land damages, etc.	{

* See Notes *B*, *C*, and *D* for details of these estimates.

"As the road progresses, furniture to the amount of $2 500 per mile of road in operation will be required, and more as the road lengthens and business increases. On its completion, no less than $400 000 will

be required to equip each division, of which there must be three, and in a few years it may be expected that a further quantity will be required, all of which must, however, depend on the amount of business.

"By the northern route, the cost of main line will be less by..... $1 364 000

"The Puebla Branch and structures at Puebla are estimated at..... 1 278 000

"Difference of cost against Puebla Line only.. $86 000

"Full details of the work are exhibited in the accompanying papers, to which reference is respectfully requested.

"TABLE 2.—QUANTITY OF EXCAVATION, EMBANKMENT, MASONRY AND TUNNELING ON THE SEVERAL PORTIONS OF THE ROAD FROM TEJERIA, *via* ORIZABA AND PUEBLA TO THE JUNCTION OF THE GUADALUPE RAILROAD.

" Portions of line.	Length of line, in miles.	Excavation, in cubic yards.	Embankment, in cubic yards.	Masonry, in cubic yards.	Tunneling in linear feet
Tejeria to Cordoba.....	58.4	881 036	1 033 690	50 095	840
Cordoba to Orizaba.....	16.3	657 194	438 822	40 822	700
Orizaba to Maltrata Summit.....	28.1	429 117	607 806	179 115	660
Maltrata Summit to Puebla.....	60.2	414 519	757 685	16 289	.....
Puebla to Junction.....	29.6	174 582	449 677	33 368	.....

Totals.....	276.5	2 975 463	3 665 731	324 803	2 200

"The country traversed by the railway will afford all the material required for its construction except iron. Timber, though not abundant throughout the line, is sufficiently so in some parts of it for the supply of all. In the estimates, suitable provision has been made for its transportation, as well as for rendering it more enduring by some of the processes usually resorted to for that purpose where timber is expensive. An interesting commentary from Hugo Fink, Esq., on the timber of Mexico is appended to this report (marked 2).

"There are some features in this line of road that require particular notice, for though for three-fourths of the distance it presents lines of easy grades and open curves, requiring few expensive bridges, cuts, or embankments, there are exceptions.

"The first of these occurs at the Jamapa River, at the village of Soledad, where a bridge is required 650 ft. in length, and the grade

line is 100 ft. above the river at its low stage. I have estimated the cost of such a structure, all of masonry, at $216 000. No difficulty will be encountered in obtaining foundations for the piers and abutments. The next bridge of any magnitude will be over the Canalita Creek, and here also a permanent structure of masonry is estimated for at the cost of $90 000. Limestone of superior quality abounds in this vicinity, it is the first we find 'in place' on the line above Vera Cruz. Inexhaustible quarries may be opened for the supply of the Vera Cruz market, for building purposes, including moles, breakwaters, forts, etc., and the quality is so good that vessels lacking return cargoes may find a profit by ballasting with it for some ports. The next expensive structure will be for crossing the Atoyac River where it breaks through the Chiquihuite Mountains. Here a deep ravine has been cut in the solid limestone rock, the great depth and precipitous sides of which present formidable obstacles to a railway. To span this chasm on the present line of location will require a bridge 300 ft. in length at an elevation of 250 ft. above the stream, but by adopting a lower line, both the great height and the length of the structure may be considerably diminished. At all events, it would seem to be a point where an iron bridge may be used to advantage, and in the estimate I have allowed $275 000 for the construction of one. (See Note *F*.)

"The crossing of the Rio Seco will require 300 ft. of bridging, at an elevation of 55 ft., which is estimated to cost $50 000. Between Cordoba and Orizaba is the deep *barranca* which is crossed by the public road near the village of Fortin, by which name it is known to many, though to others as the Barranca de Metlac. The point at which the fewest obstacles are presented to a crossing for a railway appears to be about 2¼ miles north of Fortin, where it was found to be 1 085 ft. wide at the grade line, which was 346 ft. above the stream. The rock on the west side slopes about 45°, the eastern slope being still steeper, consequently the span of the bridge can be but little reduced, except at an enormous cost for embankments. It is a fine site for a suspension bridge, and if that kind of structure was not very objectionable on railroad lines, I should recommend the construction of one at this point as the cheapest method by which this ravine can be crossed. A better, but much more expensive plan would be an 'Iron Tubular Bridge' of two or three spans, resting on piers formed of cast-iron tubes, which would be cheaper than masonry.

"No detailed plan or estimate for this viaduct has been prepared, but from such data as I have been able to collect, it may be estimated at $1 200 000. (See Note *F*.) I do not recommend its construction at an early day, for we find that, by running the line down the eastern slopes of the *barranca*, it may be crossed on a bridge 600 ft. in length, and at an elevation of 140 ft., and where it is sufficiently wide to turn

the road on a curve of 400 ft. radius in order to ascend the opposite side. The road is thus brought back to the point of the high crossing and without the admission of grades higher than 158 ft. per mile, which is not objectionable, considering that the same curvature and much higher grades are admitted above Orizaba.

"This change will reduce the cost to $400 000. After passing the *barranca* no expensive work is required, except on the 9 miles of the mountain line near Maltrata Summit and 3 miles in descending into the Acacingo Valley at Cuesta Blanca.

"In estimating the cost of work, about 50% has been added to the prices usually paid in the United States, where free labor is employed, and the same percentage, also, has been added to the cost of equipment, to cover the transportation, or the extra cost of such portions as may be manufactured in Mexico.

"A most liberal estimate has been made of the cost of track, the rails to weigh 60 lb. per yd., of a superior quality of iron, with fished joints, on sleepers, either creosoted or cyanized, to give them greater durability; this is deemed indispensable on account of the scarcity of timber in Mexico, as well as the effect of the climate upon it when not so prepared, especially in the hot and temperate portions of the country.

"The cost of railroad work in Mexico, I believe, will, after the first year or two, be very little greater than in the United States. Labor at the commencement of operations must be taken to Mexico at the expense of the parties doing the work; but when a demand for it, with constant and steady employment at fair wages, is established and generally known in Europe, and in the United States, it is but reasonable to suppose that emigration will move in that direction to the full extent that employment can be given to it; and the cost of work should then be very little, if any, greater than in the United States. Except in the hot country, a man can labor as many hours, and with as much effect, as in any other country; subsistence and clothing are not more expensive, if as much so, as in New York or Ohio. It would not, therefore, seem to be judicious to make very large contracts at the commencement of the work; otherwise all the reduction in the cost of labor would go to the benefit of the contractor, who as a first experiment would calculate on liberal prices, and insist on a large margin to meet contingencies, the most of which a slight advance will cover, after allowing for time required for traveling and cost of transportation of such labor as must be engaged in foreign countries. The instability of the Government would seem to be the greatest obstacle to cheapening labor in Mexico, but that I conclude is a risk to be borne by the Company, and not by the Contractor.

"The following is believed to be a fair estimate of the probable cost of maintaining and operating 266½ miles of railway in Mexico, with

the number of trains that may from time to time be required for its business:

"With	2	daily	trains	$365 000	per	annum.
"	4	"	"	580 000	"	"
"	6	"	"	798 000	"	"
"	8	"	"	1 015 000	"	"

"For the details of this estimate see note (marked *E*) where the number of trains for passengers and freight has been assumed to be equal, or in some cases mixed for passengers and freight.

"The data are not in my possession for estimating the present or prospective amount of trade and travel over your road.

"The foregoing estimate of the cost of constructing, maintaining, and operating it, with from 2 to 8 daily trains, each capable of conveying 200 passengers, their baggage, and the mails, in 16 hours, or 200 tons of freight in 36 hours, from Vera Cruz to the City of Mexico, will, with that of your statistical commission, afford sufficient data for investigating the financial prospects of the enterprise. From the very imperfect observations made of the amount of business, during the progress of the surveys, though a civil war was then raging, I should estimate that more than Three Million of Dollars was paid annually for the transportation, that can be better done by a railway for one-quarter of that amount.

"The maps and barometrical profiles prepared under your authority by Mr. Almazan, and handed to me a few days after the landing of the party in Mexico, were of great value, as they enabled me to place the parties on the lines of greatest promise before a reconnaissance could be made in person. To the Engineers employed in the enterprise I am under great obligations for the prompt and satisfactory execution of all the duties assigned them, whether in the field, or in the office.

"All of which is respectfully submitted,

"ANDREW TALCOTT,

"NEW YORK, MARCH 7TH, 1859." *"Chief Engineer."*

6.—SUMMARIES OF SPECIAL REPORTS, *A, B, C, D, E,* AND *F.*

In addition to his general reports, Capt. Talcott also submitted the following special reports or notes:

A.—Effective Working of Engines on Grades.—This is a study of the tractive power of locomotives to determine the most economical grades for the Maltrata Incline. It was assumed that an engine weighing 25 tons, with a tender of 20 tons, when charged with fuel and water, could take a train of 130 tons from Vera Cruz to Orizaba; thence to the Maltrata Summit an additional engine of 25 tons, constructed for that service, would be required to assist in reaching the summit.

B.—Estimate of Cost of One Mile of Track and Keeping it in Repair until Opening of Section for General Traffic.—This contains remarks on the comparative economy of best quality with inferior rails; extract from a report of the President of the Philadelphia, Wilmington and Baltimore Railroad Company, in 1858, on the subject of rails; and extracts from a report on European railways, by Colburn and Holley, relative to rails. At the time of making this report (1858-59), merchantable rails, or such as were ordinarily manufactured for the American market, could be purchased for from $33 to $41 per ton. An estimate of $70 per ton was made for rails delivered in Vera Cruz, which allowed considerable margin for changes in the market, as well as for better rails than those ordinarily made for the United States, it being assumed that good rails should last from 12 to 16 years. The experience of the Philadelphia, Wilmington and Baltimore. Philadelphia and Reading, and also of English railroads, was cited as to weight and manufacture of rails, and makes interesting reading, showing that rail troubles were not unknown at that time.

The cost of 1 mile of track for the Mexico and Pacific Railroad was assumed at $14 000, the weight of rail per yard being 60 lb., although it is not specifically stated, but is inferred from the quantity given per mile.

This report contained the following estimate of the cost of 1 mile of track and of keeping it in repair until the opening of the section for general traffic:

2 440 cu. yd. of ballast at 60 cents	$1 464
2 750 cross-ties at 85 cents	2 337
95 tons of rails, extra quality, landed at Vera Cruz, at $70	6 650
6 tons of fish-plates at $80	480
1½ tons of bolts and nuts at $120	150
8 000 lb. of spikes	400
Dressing surface of roadway and preparing for the track	150
Transporting materials for 1 mile (average)	1 250
Laying 1 mile of track	600
Extra cost of switches per mile	125
Total cost of 1 mile	$13 606

Brought forward	$13 606
For repairs of slopes during construction, and keeping track in repair	394
Total cost of 1 mile with repairs	$14 000
Cost of rails, spikes, plates, etc.	$7 805
Cost of cross-ties	2 337
Total cost of materials	$10 142
Ballast	1 464
Labor and transportation	2 394
Total cost of 1 mile	$14 000
Cost of iron for 280 miles	$2 185 400

C.—Buildings and Structures for Stations.—The sum of $585 000 was estimated for the buildings and structures required for the principal stations of the railway from Vera Cruz *via* Orizaba and Puebla to the City of Mexico, and for way stations. Water stations, engine stalls, and repair shops were included in this item. The largest proposed expenditure was at the City of Mexico, where the sum allowed was $237 000.

D.—Equipment.—It was not thought probable that more than one passenger train daily would be required for many years, except, perhaps, on the arrival of steam packets at Vera Cruz, when an extra might be needed, and that was provided for in the following estimate. It was also estimated that one freight train could take from Vera Cruz, over any grade east of Orizaba, 160 tons of gross, or 100 tons of freight, which is equivalent to 30 000 tons per annum, a quantity greater by one-half than the present imports at Vera Cruz (1858), estimated at 20 000 tons annually. It was thought probable, however, that on the opening of the entire road, from Vera Cruz to the City of Mexico, a second freight train daily would be needed. The sum of $1 260 000 was allowed for equipment, detailed as follows:

54 engines	at	$8 000 =	$432 000
36 passenger cars	"	2 500 =	90 000
18 mail and baggage cars	"	1 500 =	27 000
90 house cars	"	700 =	63 000
60 platform cars	"	500 =	30 000
Carried forward			$642 000

Brought forward			$642 000
30 gravel cars	at	400 =	12 000
30 crank cars	"	150 =	4 500
30 hand cars	"	50 =	1 500
Cost in the United States		=	$660 000
Add 50% for cost at Vera Cruz		=	330 000
			$990 000
6 turn-tables, stationary engines, etc		=	210 000
4 mountain engines		=	60 000
Total			$1 260 000

E.—Cost of Maintaining and Operating One Mile of Railroad in Mexico.—This cost was estimated to range from $365 000 per annum for two daily trains to $1 015 000 for eight trains.

F.—Iron Girder Bridges.—Letter from William Fairbairn.—In Capt. Talcott's report, mention is made of two high river crossings, necessitating bold and costly bridges. One, the crossing of the Rio Atoyac, between Paso del Macho (Mule Pass) and Cordoba, the other, the crossing of the Barranca de Metlac, between Cordoba and Orizaba, both deep chasms in which flow torrential streams during the rainy season, but which are dry the remainder of the year.

The Rio Atoyac rises in the Chiquihuite Mountains, and flowing in a southeasterly direction, joins the Rios Chiquihuite and de San Alejo, which empty into the Rio Jamapa. The proposed railroad crossing was 300 ft. long and 300 ft. high.

The Rio de Metlac rises among the fissures of the Pico de Orizaba, and, after a sinuous course, is lost in the plains adjoining the slopes of the Cacalote and Chiquihuite Mountains. It is crossed by the Vera Cruz-Mexico City highway near the Village of Fortin. This crossing was made by a series of zigzags, down one side and up the other, the opposite banks being united by a stone bridge. At the place of the crossing of the original line of survey, this ravine is more than 1 000 ft. wide and about 350 ft. deep below the adjoining plains of Cordoba on the east and those of Orizaba on the west.

At first a suspension bridge was suggested for the railroad crossing, but this design was afterward changed to an iron tubular

bridge after consultation with Mr. William Fairbairn, the well-known English engineer of the last century.

The following extract from the report of Capt. Talcott relative to the cost of tubular bridges for the two crossings mentioned is of interest in these days of cantilever structures:

From the letter of Mr. Fairbairn, * * * it appears that iron plates for a tubular bridge of 317 ft. span will cost in Liverpool £15 333 sterling, and that 1 034 ft., that is, one span of 400 ft. and two of 317 ft., would cost £57 166. One pier of masonry in the Barranca de Metlac, 346 ft. in height, would cost $225 000. One of cast-iron columns under a permanent compression of 1 ton per sq. in. would require 1 875 sq. in. of iron at the bottom, and 1 500 sq. in. at the top, equal to 2 tons per ft. of height, or 850 tons of cast-iron columns, to which should be added for the connection 150 tons, or, in round numbers, for one pier of cast iron, 1 000 tons, mostly of cast iron, which I estimate can be purchased in Liverpool, all fitted, for £9 000. For two piers, the cost of each would be about one-sixth less, or for the two £15 000. From these data I infer that my estimate of $1 200 000 for bridging the *barranca* is a very liberal one.

"MANCHESTER, NOV. 26TH, 1858.

"SIR.—In reply to your letter of 3rd I have to refer you to the annexed pen sketch of the bridges I would propose for crossing the ravines or rivers, on the line of railway between Vera Cruz and Mexico. I assume that, in crossing these valleys, it will be a single line of rails, and should this be the case the following will enable you to form a correct idea of the cost of the ironwork forming the superstructure. You will observe that I have divided the wide ravine of 950 ft. into three spaces, as being much cheaper, but I have given you the cost both ways, in order that you may draw your own conclusions as to which is the most eligible, or most expedient to be adopted.

"For the 400-ft. span we have as under:

"Tubular bridge of 400 ft. span, prepared in sections and delivered in Liverpool ready for re-construction including all the plates, bolts, rivets and expansion apparatus, the whole complete, about 1 250 tons....	£26 500
"Also, tubular bridge in three spans of 317 ft. each, collectively 950 ft. = 2 150 tons and delivered, as above..	46 000
"Total for both bridges delivered in Liverpool.....	£72 500

"To make the latter bridge of two spans, the weight will be 3 000 tons, and will cost with expansion apparatus, etc., from £65 000 to £66 000, making a difference of £20 000 in the cost of a bridge of two spans, compared with one of three spans.

"The computed strength of these tubes will be 8 tons per lin. ft., or 3 200 tons for the 400-ft. spans, and 7 600 tons for the three spans. The piers, *A A*, may be made of iron if you prefer it. For all your commands

"I am,

"Dear Sir,

"Yours sincerely,

"M. E. LYONS, ESQ., C. E." "WM. FAIRBAIRN."

Although Capt. Talcott did not recommend the immediate construction of the high Metlac Bridge, and, as an alternative, proposed a lower bridge by running the line down along the eastern side of the *barranca* to a suitable crossing and then ascending along the opposite side, the original plan of building the high bridge was adhered to for some time.

On April 26th, 1866, nearly 8 years after the report of William Fairbairn, the cornerstone was laid with appropriate ceremonies, the occasion being referred to as the "Grand Demonstration, Cornerstone Laying of Big Bridge", at which were present Señor Don Antonio Escandon, the Prefect of Orizaba, Engineers William Lloyd, Sebastian Wimmer, and others. The "demonstration" was followed by a dinner and dance.

Following this function, a pronounced earthquake occurred on May 10th, 1866, exactly 2 weeks after, which phenomenon caused the immediate abandonment of the original project, fearing for such a structure the disastrous consequences of a repetition.

The alternative line was then substituted and made a part of the location between Cordoba and Orizaba, which was run in 1866 by Gen. H. T. Douglas, an assistant of Capt. Talcott.

Under date of June 28th, 1871, Mr. William Cross Buchanan, who at that time was Chief Engineer of the Mexican Railway, as then constituted, approved this change and designed the structure crossing the *barranca,* known as the Metlac Viaduct. It consists of nine spans, each of 50 ft., and is built on a curve with a radius of 325 ft. (17° 40′), with the track at an elevation of 80 ft. above the level of the river which gives the name to the ravine. The bridge was constructed at the famous ironworks at Crumlin, England. Each pier was composed of eight cast-iron columns, of which the inner four were vertical, and the outer four had an inclination or batter of 1 in 8. These piers carried the plate girders, and these, in turn, carried the track, cross-ties, and rails.

7.—Maps, Profiles, Plans, and Estimates.

Accompanying Capt. Talcott's report was a general map showing the entire line, on a scale of 1 in. = 5 miles. There were also detailed maps of the nine divisions into which the line was divided, generally between the large cities as, Vera Cruz-Soledad; Soledad-Cordoba; Cordoba-Orizaba; these maps were drawn to a scale of 1 in. = 3 000 ft., except that for the Orizaba-Maltrata Summit Division, which was 1 in. = 1 000 ft. There was also a map of the public road from Mexico to San Martin on the larger scale.

In addition, there were eight profiles of the various divisions, and plans of proposed buildings and bridges.

There was also a detailed estimate by mile sections of the cost of graduation and masonry, summarized by divisions, the names of these being given in Capt. Talcott's report in Tables 1 and 2, under the headings, "Locality and Portions of Line."

The graduation was divided into three classes: excavation, hauled into embankment, and borrowed material. On the Tejeria-Cordoba Division, 58¼ miles, the assumed unit prices per cubic yard for excavation were, between Tejeria and Purga, about 10 miles, 25 cents; between Purga and Atoyac, along the foot-hills of the Chiquihuite Mountains, about 31 miles, 50 cents; between Atoyac and east of Paraje Nuevo, about 8 miles, in the Chiquihuite Mountains, $1.50; the material at the latter place being limestone rock. On the remaining 8 miles, the excavation price was generally 30 cents, although there was some at 50 cents and some at $1.50. For "hauled into embankment" (extra haul), the assumed price ranged from 3 to 27 cents; and for "borrowed material", 25 and 30 cents. Bridge masonry was estimated at $10, ordinary masonry at $8, and dry masonry at $4. There were two tunnels on this Division, respectively, 460 and 380 ft. long, a total of 840 ft., which were estimated at $75 per lin. ft. The cost per mile ranged from $926.80 for Section No. 8 to $78 360.58 for Section No. 57, where no tunneling or high viaducts occurred. The Atoyac Bridge Section, No. 45, was estimated to cost $304 268.15, of which $275 000 was for the bridge. About one-half the estimated cost of this Division, more than $832 000, was concentrated at four points, the crossings of the Jamapa, Chiquihuite, Atoyac, and Seco Rivers, making the average cost of 54 miles about $13 000 per mile, exclusive of track.

About the same prices were used on the Cordoba-Orizaba Division, 16.3 miles, *via* the line run down the sides of the Barranca de Metlac. Conglomerate was estimated at $1 and tepetate at 50 cents. Section No. 5, containing 315 435 cu. yd. of excavation and hauled embankment, was estimated at $200 120.83, and Section No. 8, which includes the Metlac Bridge, was calculated at $400 113.56. One tunnel, 700 ft. long, was estimated at $75 per lin. ft.

On the Maltrata Pass-Orizaba Division, 27 miles, which includes the world-renowned "Maltrata Incline", with grades of 212 ft. (and more) per mile, the excavation price was generally $1.25, with some material at 25 and some at 45 cents. Hauled embankment ranged from 3 to 16 cents, and borrowed material was 30 cents. Masonry was $8, $12, and $13, and retaining wall was $2.50. There were three tunnels, aggregating 660 lin. ft., estimated at $75 per lin. ft. The estimated

COST OF GRADING AND MASONRY BY ONE-MILE SECTIONS

MEXICO PACIFIC RAILROAD
EASTERN DIVISION
FROM
VERA CRUZ TO MEXICO
EXPLORATIONS, SURVEYS
AND
ESTIMATES
1858

cost of Section No. 7 was $194 832.85. A large quantity of retaining wall was estimated on this Division, 129 120 cu. yd.

The next division extends from the Maltrata Summit to the junction with the Puebla Branch near Molino San Diego, 68½ miles. The excavation and borrow prices were generally 25 cents each, although there was some excavation at 50, 61, and 80 cents, the latter being lava. There was also a small quantity of borrow at 33 cents. The estimate for Section No. 38 was only $183.85, with many less than $1 000. That for Section 51 was $86 136.02. For the first 44 miles the average cost was $3 300, and for the entire 68 miles, less than $7 000 per mile.

On the direct line from the Maltrata Summit to Puebla, 61¼ miles, the excavation prices ranged somewhat higher, 25, 30, 50, 60 cents, and $1.25, the hauled embankment, from 2 to 18 cents, and the borrowed material from 25 to 50 cents. Generally, the cost per mile was low, although it was high on two sections; on No. 9 the estimated cost was $82 642.00, and on No. 10, it was $145 615.91. The average cost per mile was $10 000.

On the Puebla Branch, 29 miles, higher unit prices were assumed, uniformly 40 cents for excavation, except on Sections Nos. 27 and 28, where 80 cents was taken for tepetate. Hauled embankment was from 2 to 13 cents, and borrowed material, 30 cents.

On the division from the junction of the Puebla Branch to Mexico, called the Western Division, 83 miles, the ruling price for excavation and borrowed material was 25 cents. The average estimated cost per mile was less than $3 000.

Grades.—With the exception of the descending grades between Paso Tablo and Atoyac and the crossing of the Barranca de Metlac between Cordoba and Orizaba, there is a continuous ascent from Vera Cruz to Boca del Monte, a rise of 8 101 ft. in 111 miles. Between Vera Cruz and Paso Tablo, the range is from level to 110 ft. per mile. In constructing the railroad, a change was made, passing through Paso del Macho. In the vicinity of Cordoba and Orizaba, grades of 132 ft. per mile were proposed, and on the Maltrata Incline, 211 ft. per mile, or 4 per cent. Between Boca del Monte and the City of Mexico the grades are undulating, adapted to the configuration of the surface, the maximum used, in isolated cases, being 89 ft. per mile, but generally, of course, much lighter.

APPENDIX A

Extracts from Report of Mr. M. E. Lyons,* Principal Assistant Engineer.

"Shortly after the arrival of the engineer corps in Vera Cruz, they were instructed to proceed to Tejeria and encamp in the most eligible place in the neighborhood, until such time as arrangements could be made for transporting them to the interior, for, owing to the loss of the mails by the previous steamer, Mr. Escandon had not been duly informed of the departure of the engineers from the States; and as no means of transportation had been provided previous to their arrival, there was a consequent delay of nearly 3 weeks.

"This time was not wholly lost, however, as the party had to be drilled into camp life, surveying instruments had to be tested and adjusted, and the corps more perfectly organized.

"The threatened civil war, which afterward unhappily broke out, affected disastrously all the commercial interests of the Republic. The stories which reached us of the attacks made on travelers, the assaults committed, and robberies perpetrated on the highway in midday, made the party exceedingly wary, and induced us to form a semi-military organization, for our mutual protection, which we upheld ever afterward during our stay in the Republic.

"Sentries were mounted and relieved every 2 hours, during the night, and this was continued without intermission at each and every encampment, and to the vigilance exercised at all times the party no doubt owe their entire exemption from harm.

"The problem proposed for our solution is to find the most direct and practicable line for a railroad between the commercial and the political capitals of the Republic. Mr. Almazan furnishes a valuable map and barometric profiles which he had prepared of the Atlantic slopes. Between the mountains of Orizaba and Perote, the chain of the Cordilleras appears to be very high, and it is therefore deemed useless to make a reconnaissance of the depressions in the chain between these points. Northward of Perote and southward of the Peak of Orizaba the depressions seem to be deeper and more accessible. Two parties are detailed for the duty of examining these passes, and reporting on their practicability for railway purposes: Mr. Richards in charge of the party sent to examine the passes north of Perote, and Mr. Stoddart to examine those south of Orizaba.

"The route in the vicinity of the national road between Vera Cruz and Jalapa presents very unfavorable ground for a railroad. From San Juan, the western terminus of the existing railroad to Paso de Ovejas, passing through Zopilote, Tierra Colorada, and Tolome, it is hilly and unfavorable. The stream and valley of the Paso de Ovejas would be difficult and expensive. The country between Paso de Ovejas and Puente Nacional is thickly covered with underbrush of a tropical growth.

"The *barranca* at the Puente Nacional is a serious obstacle to a railroad, being about 1 500 ft. wide, and 250 ft. deep. For about 5 miles west of the Puente Nacional the ground is represented to be

* Mr. Lyons, formerly of Reading, Pa., was Capt. Talcott's assistant for many years.

favorable, and then becomes broken and unfavorable. At Plan del Rio we encounter another deep *barranca,* but not quite so wide as that of the Puente Nacional. At Rancho Cerro Gordo it is represented to be almost an impossible ground in a commercial sense for a railroad.

"A little west of this place, and near Mirador to Encierro, there exists a wide and deep valley descending to Dos Rios with a slope of some 240 ft. per mile, and to a depth of 500 ft. From this point to Jalapa is broken, but there is no unsurmountable obstacle in the way. From Jalapa to the summit of the Cordilleras at Las Vigas is a continuous mountain side, broken in places by ravines and water-courses, descending the mountain slopes and intersecting the route nearly at right angles.

"I cannot do better than give an extract from the report of the Engineer charged with the duty of exploring these mountain passes:

"'It [the route] certainly impressed me very unfavorably from an engineering point of view. The route from Las Vigas, round by the base of Perote [Mountain] toward Jalapa, seems—as far as I could judge from a very slight examination, which was all I could give—the most favorable; all cuttings, however, will be through rock of a volcanic nature. It comes to the surface in all directions; in many cases the débris would make very fine ballast, requiring little or no breaking. Possibly a line might be had from Las Vigas by Perote Mountain to Jalapa, with a general grade of 170 ft. to the mile, but it would be both crooked and very expensive. There seemed to be a lower gap to the north of Las Vigas. I went to examine it at one point, and Mr. Stack at another. The fog came on very thick before the exploration could be completed, but, from what I could see, it appeared about the roughest country I ever saw. The ravines were from 500 to 800 ft. deep, and the sides so steep that a man could with difficulty stand on them. This lower summit is at the head of the Canada de Actopan; up the banks of this river it has been stated that a route could be obtained; it might, possibly, but the Rio de Actopan falls into the sea considerably north of Vera Cruz, and there might be considerable difficulty in raising it out of the valley to get to Vera Cruz, except the river was practicable to the sea, which would, of course, lengthen the line considerably.'

"'From what I afterwards saw of river routes, I do not think them well calculated for railroad lines. Even if a line could be had up the Actopan River there would be great difficulty at and near the gap in question. It would require a considerable deal of exploration to pronounce on the capabilities of the region, and time did not allow me to examine it, as it ought to have been, but my general idea is that it is the worst country I ever saw to try to get a line of railway through.'

"'From Las Vigas the party returned to Jalapa, and spent some time in looking around there. It was supposed that a line might be had down a river that flows beneath the Puente Nacional, but the same river was crossed by the party two days afterward on the route from Jalapa to Cordoba. It is most likely impracticable to follow this river, if the whole of it be like the place where the party crossed it. It flows at the bottom of a *barranca* from 800 to 1 000 ft. deep. The sides often sheer cliffs from 100 to 300 ft. deep and upward. There

is no way out of the *barranca* except by a steep zigzag mule path. The rest of the country from this *barranca* to San Juan Coscomatepec is more or less broken and rugged. From San Juan Coscomatepec to Cordoba our path lay over more even ground, and formed almost a regular descending plane, crossed occasionally by small streams till we reached Cordoba.'"

Mr. Almazan, the Mexican engineer, who explored this section of country north of the Cofre de Perote, states his views in reference to the Jalapa route in his report, Appendix *B*, to which the reader's attention is directed.

ADDITIONAL EXTRACTS FROM MR. LYONS' REPORT.

"Previous to making any detailed surveys, it became necessary to determine the most practicable pass in the mountains south of the Peak of Orizaba. There were three passes which might be approached from the valleys of Ingenio, Encinal, and Maltrata. The first is the Pass of San Antonio.

"*Pass of San Antonio.*—This is the nearest to the Peak of Orizaba. The summit reached the altitude of 9 200 ft. above the sea, being more than 1 000 ft. higher than the table-land beyond. This additional ascent, over what was necessary to attain to the table-land, was a fatal objection to the adoption of this pass.

"The second one examined was the next one immediately south of the San Antonio Pass and known as the Maltrata Pass.

"*Maltrata Pass.*—The altitude of this pass was found, by barometrical measurement, to be 8 110 ft. above the sea, being at the level of the table-lands, and involving, therefore, no descent to reach them, so that when the line reached this altitude the difficulties of the Cordilleras might be said to have been fully overcome.

"*Aguila Pass.*—This was the next pass examined, its altitude being nearly the same as that of Maltrata, with this difference, however, that when the difficulty of encountering this elevation was overcome, a descent into a valley west of the summit has to be made, and then an ascent to a second summit followed by a second descent to the table-lands.

"*The Aculzingo Summit.*—This summit was also examined. The summit of the first *cumbres* was lower than any of the previous passes examined, being only 7 580 ft. above the sea; but from this summit, a descent had to be made to the valley of the Puente Colorado, then an ascent to a second summit, nearly as elevated as the Maltrata Pass, then a descent to the Canada de Ystapa, followed by another ascent to the summit beyond, from which another descent was necessary to reach the valley of San Agustin de Palmar. It became very evident that the farther south our examinations extended, the more broken was the country encountered, and that we had not only one summit to overcome but several. The Maltrata Pass was the only summit examined where, the difficulties of the first ascent being overcome, no others presented themselves, and the line ran directly on the plains.

"On further examination of this Maltrata route, we exceeded our expectations by finding gradually ascending valleys, over which the road could be carried to a considerable elevation before encountering

the obstacles of a mountain line, but this portion of the line will be more minutely described hereafter.

"Having thus accomplished what was deemed the most difficult and interesting portion of our duties, our attention was turned to discovering the most feasible line from Tejeria (the point decided on for diverging from the San Juan Railroad) to the Maltrata Pass. A great obstacle stood in our way. The Chiquihuite Mountains, which lie nearly midway between the crest of the Cordillera and the sea, had to be turned either to the north or south, or entered through the gap cut by the Rio Atoyac. Mr. Almazan had previously examined the route north of the Chiquihuite Mountains, and subsequent examinations fully corroborated the views expressed by him in his report.

"A route to the south of the Chiquihuite range had also been examined. This would cross the Jamapa River at the village of that name, the Atoyac River at Cotastla, and the Obispo River at Paso Obispo. This route was favorable, with the exception of the portion of the line between the eastern bank of the Atoyac and the Village of Los Negritos, where the ground was extremely broken and unfavorable. Another route was suggested; this would diverge from the San Juan Railroad at a point 4 miles from Vera Cruz, and, crossing the river a short distance below the confluence of the Atoyac and Jamapa, thence occupying the divide between the Rio Blanco and Rio Obispo, the line might be run to a point opposite Cordoba, with very little bridging or culvert masonry. This route would involve a considerable deflection to the south, and, therefore, might increase the length of the line from Vera Cruz to Cordoba by at least 10 miles.

"It having been thus determined: First, that the Maltrata Pass, was the best one for the railroad for many miles south of the Peak of Orizaba; second, that the line must pass through the defile of Ingenio; and third, that a line passing through the gap where the River Atoyac breaks through the Chiquihuite Mountains would offer the shortest practicable line between Vera Cruz and Ingenio.

"The party received instructions early in April, 1858, to adopt that portion of the San Juan Railroad lying between Vera Cruz and Tejeria, and, from this initial point, run a line over the most favorable ground to the Atoyac Gap in the Chiquihuite Mountains, thence to Cordoba, and through the Ingenio Valley to the Maltrata Summit.

"Previous, however, to the location of this line, an experimental line had been run from Camaron to San Juan de la Punta, and also reconnaissance made of the country in a straight line between La Soledad and San Juan de la Punta, all of which went to prove that the country between the points referred to was very much broken and nearly impracticable for railway purposes.

"The line located in obedience to the above instructions diverges from the San Juan Railroad ½ mile west of the Tejeria station on that road, and runs thence in a southwesterly direction and in a very direct line, passing a little to the north of Rancho Nuevo, Mata Cordera, La Purga, Arroyo de Piedra, Mata Judio, to the considerable village of La Soledad, where it crosses the River Jamapa by a bridge, 102 ft. high and 150 ft. long. The first 6 miles of this line crosses low sand hills and valleys, which, although covered at that time with verdure, were once the shifting sands blown up from the

Gulf of Mexico. At the end of these 6 miles, the line enters on ground of a new and peculiar formation, called, in Mexico, 'tepetate', a name applied to the drift or deposit of detritus, the débris of the rock which forms the materials of the Cordilleras. This detritus extends to an immense depth. In the first 10 or 12 ft. from the surface there are water-worn stones and sand cemented together; below this, the material is composed of gravel, then sand, and, lower still, sand of a very fine quality. This tepetate rock is soft when first removed from its bed, but when exposed to the sun for a few days becomes harder, and might be used as a building stone in places where it would not be subjected to great pressure. When first quarried it is easily pulverized, and makes an excellent constituent for mortar or cement.

"The line from Tejeria to La Soledad, as before described, is undulating, the heaviest grade at any place being 60 ft. per mile. The line after crossing the Jamapa River at La Soledad occupies the south bank of that stream. Thus availing ourselves of a most remarkable natural feature in this section of country, which is that the southern bank of the Jamapa River is the ridge of the water-shed from which the streams fall into the Rio Atoyac, so that by running the line as near the bank of the river as practicable, and occupying the plain at the point where it began to resolve itself into ridge and valley, a way was found for the roadbed already prepared by natural means. The line, therefore, runs from the crossing of the Jamapa for a distance of 17 miles near the bank of that river, the work of graduation and masonry on that portion of the line being exceedingly light; the grades, however, are heavy, rising at first 70 ft. per mile, then 80, 85, 90, and finally running up to 110 ft. per mile. The line has here reached a point 36 miles from Tejeria, where the Jamapa runs no longer in our true direction, but takes a northwest course to Pueblo Viejo. The line at this point leaves the bank of the river, and runs southwest, crossing a stream at Paso Tablo and encountering near the Rancho Santa Teresa, the Rio de San Alejo, an inconsiderable stream at this point, running in a *barranca* of no great depth. From the crossing of the San Alejo, the line descends to the Canalita, a small stream which takes its rise near the Hacienda Defensa and runs along the eastern base of the Chiquihuite range. The line crosses the Canalita, at an elevation of 90 ft. and thence it occupies the slope of the Chiquihuite Mountains to the Gap of the Atoyac. From the crossing of the Jamapa River at La Soledad to the crossing of the San Alejo at Santa Teresa the line is comparatively open and free from woodland, if we except a few groves of trees which here and there dot the plain; not so, however, the ground between the Rio San Alejo and the Chiquihuite Mountains; this country is thickly wooded, with underbrush below, and parasitical plants and creeping vines hanging to the branches of the trees above, in places almost excluding the light and rendering it a matter of extreme difficulty to discover the best route, and to cut a way through it. The Chiquihuite Mountains are densely wooded. Many of these woods will be available for the railroad. The live oak which here abounds will form a lasting sill, and fuel for a century to come can be obtained on these mountains.

"The line, as above stated, occupies the eastern slope of the Chiquihuites, from the crossing of the Canalita to the gap made by

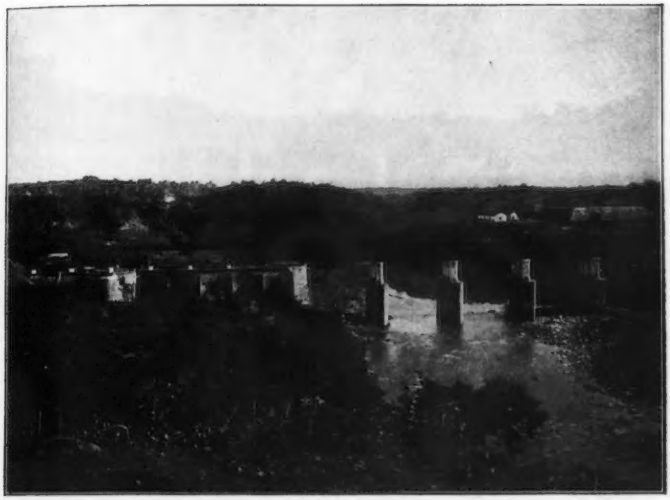

FIG. 3.—SOLEDAD BRIDGE, OVER JAMAPA RIVER, 42 KM. (26 MILES) WEST OF VERA CRUZ. ORIGINALLY A HIGHWAY BRIDGE COSTING $328 109. OVER THIS BRIDGE MR. M. E. LYONS BUILT A WOODEN STRUCTURE COSTING $200 000, WHICH LASTED UNTIL 1868, WHEN IT WAS REPLACED BY AN IRON BRIDGE.

FIG. 4.—SAN ALEJO BRIDGE, OVER THE RIO DE SAN ALEJO, 82 KM. (51 MILES) WEST OF VERA CRUZ. 100 METERS (328 FT.) LONG.

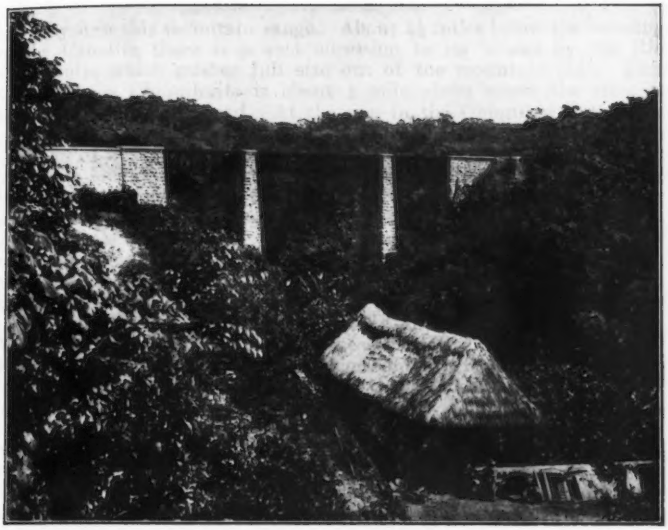

FIG. 5.—CHIQUIHUITE BRIDGE, OVER RIO CHIQUIHUITE, 83 KM. (51½ MILES) WEST OF VERA CRUZ. 67 METERS (220 FT.) LONG.

FIG. 6.—ATOYAC BRIDGE, OVER RIO ATOYAC, 86 KM. (53½ MILES) WEST OF VERA CRUZ. 100 METERS (328 FT.) LONG.

the Atoyac in this mountain range. About 1½ miles below the crossing of the Canalita there is a vast accession to its waters by the Rio Chiquihuite which gushes full size out of the mountain side. This source of the Chiquihuite is about ¼ mile above where the river is bridged by the public road. At the gap in the Chiquihuite, the line crosses from the north to the south bank of the Atoyac River, at an elevation of 304 ft. above the water. It will be possible hereafter to lessen the height of this bridge by increasing the grade—now nearly level—on both sides of the Atoyac River, and to introduce such other modifications of the line as future explorations may prove advisable. About a mile west of the crossing of the Atoyac the line leaves the mountain side and enters the Valley of El Potrero; then, occupying the divide between the waters of the Atoyac and the Seco, it passes through a densely wooded country with light earthwork, and but little masonry, till it reaches the Rio Seco, a short distance west of the Village of Peñuela. The ground rose so rapidly in the Valley of El Potrero, although but little indication of this fact would be given to the traveler with his unassisted eye, that grades of 132 ft. per mile became necessary. The line crosses the Rio Seco 60 ft. above the water, and then, curving to the south, intersects the public road a short distance west of Peñuela, and passing over some broken ground to San Miguelito, from which it runs to a point opposite the City of Cordoba, occupying a narrow ridge which offers both favorable ground and alignment. The grade from San Miguelito to Cordoba is 132 ft. per mile.

"An attempt was made to carry the road in a direct course from the point opposite Cordoba to Las Animas, but it was found that a grade steeper than 132 ft. to the mile would be required, and therefore it was deemed advisable, rather than increase this grade, to make a slight detour for the purpose of lengthening the line by way of Dos Caminos to Animas, and thence to the crossing of the Barranca de Metlac. It is probable that on final location this line would not cross the stream near San Miguelito, but would occupy the ridge nearer to the public road, and run closer to the City of Cordoba than the present line, which runs nearly a mile south of that city.

"The country is tolerably open from the crossing of the Rio Seco to the City of Cordoba.

"This city has a population of about 5 000 to 6 000. From its general appearance it seems to have had more prosperous days. It contains a very fine parochial church, several religious institutions, a barracks, some very good stores, and hotels. The soil in the vicinity seems to be very rich, but it is not much cultivated except in the immediate vicinity of the city, where vegetables, bananas, oranges, and coffee are raised. The plains which surround the city for many a square league are used for pasturage.

"The line has been described to the point where it crosses the Barranca de Metlac. This *barranca* is the most formidable obstacle to be encountered at any point between Vera Cruz and Orizaba. It is a deep gorge cut beneath the level of the plain. From the grade points on each bank, the distance is 1 085 ft. across, and the depth, from the grade to the level of the water in the bottom, is 346 ft.

"The subject of bridging this *barranca* requires considerable study,

and the preparation of plans and details in order that the subject may be viewed in all its bearings, and the question of economy and stability may be fully discussed.

"The erection of such a bridge will necessarily occupy much time, and therefore examinations were made, to ascertain if it were practicable to obviate the building of this high bridge, or to ascertain if some temporary expedient could not be resorted to, by which the road could be worked, before the high bridge was completed. A line with a descending grade, was run down the eastern slope of the *barranca*, and advantage taken of a point where a bend occurs in the stream, and where the valley widens, to cross the river at that point, and curving to the south on a radius of 400 ft., to the opposite bank of the *barranca*, ascending thence to the plain. This line would cross the river with a bridge 500 ft. long, and 140 ft. high, but it would add 2 miles to the length of the road.

"On gaining the western slope of the *barranca*, the line occupies a favorable valley, and, with the exception of crossing three or four streams, meets with no important obstruction until it reaches Cocolapan, and the City of Orizaba. From the Barranca de Metlac to Cocolapan the grades do not exceed 106 ft. to the mile.

"From the City of Orizaba westward the line runs through valleys bounded by majestic mountains, the presence of which greatly disturbs preconceived ideas of distance, for wide valleys are dwarfed in their vicinity to the appearance of one-third their actual width.

"The line occupies nearly the center of the Ingenio Valley, and west of the Town of Ingenio it curves to the north, and runs through the Valley of Encinal, passing a little to the west of the *hacienda* of that name. This valley rises so abruptly that it becomes necessary to introduce grades of 200 ft. to the mile; near this the head of the line curves to the south and enters on the slope of the *barranca* which leads from the Valley of Maltrata into that of the Encinal, and after encountering some heavy work, in rounding one or two bluffs, it emerges from this narrow gorge into the Valley of Maltrata at the north end of which stands the Indian village of the same name, containing a population of several hundred.

"The line of survey touches the north end of the village, where a light grade is introduced to enable the company to make a stopping place, and also to give the engine an opportunity to accumulate steam to propel the train up the steep grades which intervene between Maltrata Village and Maltrata Pass. From Maltrata the line ascends, with a grade of 203 ft. to the mile, for 3 miles, where another piece of light grade is introduced for the purpose before mentioned. The line has now reached an altitude of 6 100 ft. above the level of the sea; the valleys reach no higher, and the remainder of the ascent must be made on the steep and rugged sides of the mountain. Fortunately, there is only 8 miles of mountain line, a result certainly not looked for when we first viewed these formidable barriers from Tejeria.

"The ascent from the head of the Maltrata Valley to the Maltrata Summit is made with grades averaging 200 ft. to the mile, increased on straight lines to 212 ft., and proportionately reduced on curves.

"From the Maltrata Pass to the City of Mexico the railway can be carried over a series of plains, some of them separated one from an-

FIG. 10.—PANORAMIC VIEW, HEIGHTS OF MALTRATA. VOLCANO OF ORIZABA IN THE DISTANCE.

other by low trap dikes, others, again, are regular steppes, one plain being at an elevation of from 200 to 300 ft. above the other, but the ascent or descent can always be made by running along the slopes of the mountains. The direct line between the Maltrata Pass and the City of Mexico would leave the important City of Puebla nearly 30 miles to the south, rendering necessary a branch line of that length to connect it with the main line.

"To obviate this, explorations were set on foot to ascertain the practicability of connecting the valleys of Puebla and Mexico, by a tolerably direct line. It was soon discovered that no practicable route for a railway lay in the vicinity of the public road near Rio Frio, which at its greatest elevation attains an altitude of 10 500 ft., or nearly 2 miles in vertical height above the level of the ocean. Explorations were also conducted in the vicinity of San Martin to ascertain the practicability of finding a route for a railroad between that point and the Hacienda San Nicholas. This line would involve the building of 14 miles of mountain line, with a uniform grade of 106 ft. per mile. It was found, moreover, that the saving in distance would not be very great, as considerable northing would have to be made, in order to turn the chain of high mountains near Apam. A line running along the base of the western slope of Mt. Malinche, and near the banks of the Rio Atoyac, presented the best line for connecting by railroad the City of Puebla with the plains of Apam. The surveyed line, therefore, was run with the view of making the City of Puebla a point on the main line of railroad. The line descended with the grade of the plain from the summit of Maltrata to Cuesta Blanca, a distance of 8 miles, over ground that required but little preparation for the roadbed. At Cuesta Blanca the line enters on the slopes of the mountains which separate the plains of Esperanza from the plains of San Agustin de Palmar, and descends with a grade of 86 ft. per mile to the latter plain, and, skirting for a distance of several miles the northern edge of the plain, it leaves the Town of San Agustin de Palmar 2 miles to the south, the Town of Quecholas about a mile to the north, and runs close to the Towns of Acacingo and Amozoc. The mountain portion of this line, some 5 miles of it, is really the only objectionable portion, for, after reaching the plains of Palmar and Acacingo, it runs with most excellent alignment and light grades to the City of Puebla. The whole of this valley is thickly populated and well cultivated, and is interspersed with towns and fine *haciendas*. The phenomenon of whirlwinds and the mirage were made familiar to us here. At several points in the valley the whirlwinds may be seen lifting the light grains of sand and forming columns 60 ft. in height which are carried in every direction by the currents of air. Some of the gentlemen were much deceived in the appearance of water. The light reflected at a favorable angle from the sand gave portions of the plain the appearance of a sheet of water, a cloud would at times intervene and the phantom lake would instantly disappear.

"The surveyed line did not enter the City of Puebla, but ran a little north of the Guadalupe hill, and a short line was afterwards surveyed to connect the main line of survey with the plaza in that city. The line of survey runs thence along the base of the mountain of Malinche (the base of which extends over a diameter of 20 miles)

and intersects a great number of *barrancas,* the floods from this elevated peak having cut deeply into the slopes of the mountain. These *barrancas,* in many cases, were as deep as they were wide, and in some places they appeared to be so narrow, that it seemed possible to jump from one side to the other, and yet they were very deep. The upper portions consist of a multitude of channels spreading out with fan-like appearance. These *barrancas* obtain their greatest depth in a few hundred yards. In the rainy season the waters run with great velocity until they are somewhat checked by the flattening of the mountain slopes; they then begin to deposit the material they held in suspension, and from that point to the banks of the Atoyac, at the base of the mountains, these *barrancas* become shallower.

"The strata of the lower portion of the mountain are hidden from view by a thick deposit of detritus, which forms the surface and constitutes the material of this and all the other mountain slopes in the neighborhood of the line of survey between Puebla and the City of Mexico. The line, after running for nearly 30 miles due north from Puebla, enters the plains of Apam, and, running a short distance south of the town and lake of that name, proceeds for many miles over nearly level plains, with light grades, and still lighter earthwork, until it reaches the point where it begins to ascend to the Otumba summit. The elevation of this summit is 8 272 ft. above the sea, and, therefore, is the highest ground over which the line passes between Vera Cruz and the Capital. The excavation through the Otumba summit will be through 'tepetate'. From the Otumba summit the line descends into the far-famed Valley of Mexico, passing near the Town of Teotihuacan, Tepexpam and a number of villages and *haciendas,* and, running for 15 miles along the shores of the salt-water lake, Texcoco, joins the Guadalupe Railroad about 3½ miles from the City of Mexico and ½ mile from the northern terminus of this little road at Guadalupe.

"The surveyed line from Puebla to Mexico describes nearly the periphery of a semicircle the center of which would be in the neighborhood of Popocatepetl. It is 112½ miles from Puebla to the junction with the Guadalupe road, and 116 miles between the two cities. The grade descending from the plains of Otumba to the Valley of Mexico is 90 ft. to the mile, but this can be reduced, and also the grades at other points, by lengthening the line where these heavy grades occur. The line passes near the Towns of San Pablo, and Santa Ana, and some 2 miles east of the ancient City of Tlaxcala. The land here produces all cereals and fruit of the temperate zone, and the plains of Apam produce the finest specimens of the aloe, or maguey plant which supplies the Cities of Puebla, Mexico, and Toluca with pulque, in which article there is an immense trade.

"The great advantage, says Baron von Humboldt, of the maguey growing on plains elevated from 7 000 to 10 000 ft. above the sea, is that it is not affected by change of climate, and that its firm vigorous leaves withstand hail, frost, and drought. A vigorous maguey plant will produce 1½ gal. of pulque per day for a period of 5 months. The Indian calculates the produce of the maguey at 150 bottles, and the value of a plant near its efflorescence at from $4 or $5 to $8. The maguey is not only the vine of the Aztec, but its fibrous leaves sup-

plied him with paper on which he painted his hieroglyphics, its prickles which terminate its leaves served for pins and nails, and were used by the heathen priests for piercing their arms in their acts of expiation. They also obtained thread from the maguey plant, and its pulpy substance, when roasted, formed the sustenance of a large portion of the population.

"The City of Mexico, containing a population estimated at from 170 000 to 200 000, stands near the center of the Valley of Mexico. The valley is of elliptical form, the greatest diameter being 48 miles, and its least diameter 32 miles. One-twentieth of its entire surface is covered with water. The whole valley, except to the north, where the railway enters it, is shut in by high porphyritic mountains.

"On mature deliberation, it was concluded to run another line from the Maltrata Pass, by way of Nopalucan and Huamantla, to join the line run by the way of Puebla on the Plains of Apam.

"This section of country was favorable for a railroad route, and if it should be finally adopted for the main trunk line, giving Puebla a branch line, it will save 19 miles in distance to travelers between Mexico and Vera Cruz over the line passing by Puebla. It will not add anything to the distance to be traveled between Puebla and Mexico, but will add 39 miles to the journey to be performed between Puebla and Vera Cruz.

"Detailed estimates of the cost of these lines, and tables of grades will be submitted in the latter portion of this report."

It will be noted that the first line of survey was through Puebla, placing that city on the main line, which route would be Vera Cruz, Boca del Monte, Maltrata Summit, Cuesta Blanca, Plains of Agustin de Palmar, Acacingo, Amozoc, Puebla, Mexico.

Later, a line was run by way of Nopalucan and Huamantla, a more northerly survey, joining the Puebla-Mexico line at what is now Apizaco.

Capt. Talcott, in his report, page 1556, apparently left the decision of the route to Señor Escandon, although he must have expressed his preference for the Puebla direct line, as shown by the following letter:

"MEXICO, April 18, 1859.

"Col. ANDREW TALCOTT, New York.

"MY DEAR COLONEL: Your letters of the 21st February and 7th March were received on the 9th of this month * * *, and also specifications of the two routes, such as you suppose the Decree of the 31st August requires of me. You are right in supposing there is no need of presenting the maps to the Government as long as the contract is not fulfilled on its part, but, in case of doing so, I see you are of the opinion that the Puebla line should be preferred to the northern line which renders a branch to Puebla indispensable * * *.

"I remain, my dear
"Col. Talcott,
"Yours very faithfully,
"ANTONIO ESCANDON."

APPENDIX B

TRANSLATION OF REPORT OF MR. PASCUAL ALMAZAN.*

"The geodetic positions of the points from which observations have been made, and of others which have been sighted upon from these, also the altitudes determined by barometric leveling, are already included in the map and profiles presented to Mr. Talcott, and for this reason I will not speak of them, except to remark briefly as to the position of Vera Cruz.

"This had been ascertained at first by its longitude and latitude as computed by Baron von Humboldt, but having computed the positions of La Soledad, Arroyo de Piedra, Santa Ana, Matacordero and Rancho Nuevo by the triangles formed with the Orizaba Peak and El Cofre de Perote, respectively, and having combined the positions so obtained with the data of partial distances and directions, the result was that, to make each of these agree with Vera Cruz, it was necessary to apply to this port a correction of nearly 1′ 4″ in arc with respect to its longitude calculated from Mexico City.

"Undoubtedly, the position of Vera Cruz is more correctly computed than that of the capital, as it is based on many data presented and discussed by Oltmans in the astronomical observations of Baron von Humboldt; therefore, the final correction with respect to the Paris or Greenwich meridian should be made on the longitude of Mexico, although in the maps in which the starting point is the meridian of this capital, as is the one made for the Escandon Railroad, the modification would be made on Vera Cruz.

"The electro-magnetic telegraph being now established between both cities, it is easy to determine by it, with all the accuracy of which the determination of local time is capable, the distance or difference in longitude between these two cities and in the same way that of several intermediate points, so as to have verification data.

"Passing now to the main object, I must say that several of the reconnaissances made have only shown a negative result, that is, it has been found to be impossible to carry the railroad through the reconnoitered places. The time spent in these reconnaissances, nevertheless, may be deemed as not wasted, because it saves the time that (had these not been made) would have been spent in taking the topography and levels of the lines, which may now be deemed as impracticable.

"In this category is that of Pueblo Viejo and Ixhuatlan south of the River Jamapa, because, the direct pass from Ixhuatlan to Orizaba not being possible, it would be necessary to go up to Coscomatepec and come down immediately to the last named city [meaning Orizaba, probably] some 400 meters. This supposes:

"1st. The necessity of passing through Orizaba (if this line is adopted), which is absurd, as the only available pass for a railroad is the Garganta del Ingenio; and

"2d. That it is possible to build a grade for the road in the stretch between Pueblo Viejo and Ocotitlan, which is really impracticable if we consider the narrowness of the pass, its sinuosities in both horizontal

* A Mexican engineer who made some reconnaissances of the Jalapa route previous to the arrival of Capt. Talcott in Mexico.

and vertical directions, and the impossibility of widening at a reasonable cost a road made in the most broken part of Sierra del Chiquihuite, an upheaved limestone formation with the probable opening toward the north, and which, therefore, presents at this place a fractured edge.

"If the route through Orizaba is selected two lines are presented for reaching this city: One which almost coincides with the present road, and another passing south of San Juan de la Punta, which may pass through Cordoba or Zapoapita. If the first is taken, because special study indicates the possibility of a passage through the hills between La Peñuela and Omealca, there will be the advantage of a cheap crossing of the Metlac River, but only at the expense of attaining the height represented by the Tuxpango slope. This will certainly involve heavy work, but it is probably best to cross at this point.

"It may be possible, if the Chicahuastla foundation is not too brittle to overcome this height as indicated in the attached figure, by giving to the route the maximum slope of the Semmering.

"To cross the Metlac River farther up than El Fortin, it is necessary to choose the route of La Peñuela and Cordoba, and the selection would probably depend on the comparison of costs respectively computed for the two routes, but the fact that passing through Zapoapita will save more than a league (4 240 meters) in the distance from Peñuela to Orizaba, should be taken into consideration.

"The selection of another line that would coincide frequently with the National road and would go through La Peñuela, or perhaps through the south of El Potrero and Amatlan, might be directed to Zapoapita or Zacatepec in the above named manner, depends on the detailed inspection of the gorge of Atoyac between El Chiquihuite and El Potrero.

"It may be possible, by turning to the north of Tres Encinos and Paso del Macho, to make with relative ease the crossings of the small rivers of San Alejo and Chiquihuite, and passing along the west bank of this, follow parallel to its course in a south-southeast direction until reaching the gorge, and there pass to the eastern bank of the Atoyac, crossing it at the easiest place to pass to the west bank and enter the lands of Potrero.

"It is truly difficult to execute these plans, and I only indicate them with the greatest reserve, because I wish to show that the railway would be shortened by about 4 leagues, which would be needed if it was attempted to go around by way of Cotastla.

"In this way the Jamapa would be crossed a short distance to the west of Medellin and taking the south bank of the river above mentioned, the point above mentioned to the north of Tres Encinos would be sought.

"Having passed the gorge of the Ingenio (for which no other pass can be substituted), the heights of Maltrata and of Aculcingo are seen to be the best for making the ascent; the first presents the advantage of the least distance to Morelos and the difficulty of passing from El Encinal to Maltrata through a deep and long gorge; the second invites because of its easy access to Aculcingo, at the foot of the mountain chain, and because in its vicinity (as may be seen on the map) is the Reyes ravine, the lowest pass for crossing the mountains, especially if a small tunnel is opened, thus further diminishing the altitude.

"If this route is selected, it would probably continue through Chapulco, to Carmen or to El Camero and other points that will be shown on the small-scale map that is being prepared.

"The line from San Antonio de Arriba where the barometer indicates 511 mm. is, of course, impracticable.*

"The river of Santa Catalina which belongs to the western slope of the mountain ranges and begins about 3 leagues south of the *hacienda* of San Diego would make the route of considerable length, and has at its highest point about the same altitude as that of Aculcingo, and, after ascending it, it would be necessary to descend about 500 meters to the south, only to go up the same distance by the Tehuacan route.

"It seems, therefore, that this line should not be examined.

"Between the bed of the Jamapa River and the National Bridge there are no favorable routes by which to ascend to the central plateau, and, for this reason, the examination of this region could be useful only if an easy access was found to reach a considerable height, and if, furthermore, it were easy to pass from this point to the route to be selected in the direction of Orizaba or Jalapa; but this second condition cannot be considered, because, whether running north or south, it is necessary to cross the many rivers and ravines of great depth that descend from the Cofre and Orizaba peaks, respectively.

"There remains, therefore, only the line through Jalapa, which on the National Road presents the considerable ravines of Paso de Ovejas, Puente Nacional, Plan del Rio and Dos Rios, the difficult roundabout route of Cerro Gordo, and an extremely broken section from San Juan and El Zopilote to Tolome. I believe this line also should not occupy the attention of the engineers.

"This does not apply to the Actopan River which can be reached by describing a quadrant from the west of Antigua up to the Actopan Bridge, crossing there the river of this name to take advantage of the plain of this same town, recrossing the river in front of Saetal and continuing to the west on the course of the Abas or on the adjoining argillaceous formations until reaching the height of Las Vigas.

"This line presents the advantages of a continuous ascent without the necessity, in any case, of losing any of the altitude gained; the advantage of being on the route that most directly, and therefore, with the least length of line, leads toward Mexico; and last, the advantage of crossing the State of Vera Cruz on lands of small value.

"The disadvantages of this route are that it deprives the railroad of the commercial branch to Oaxaca and of frequently having to form the roadbed on lava formation where cuts are difficult and would constantly require filling, thus losing the advantages to be had in railroad construction when a line can be run where the cuts are equal to the fills.

"There is also another feature that might endanger the stability of the road. It seems that the lava formation is submarine, that is, the outside was suddenly chilled so that the crust was unable to contract, and when the interior of the current diminished in volume, many cavities were formed, frequently very near the surface, which in places have been uncovered by the mechanical breaking of their light shells

* The altitude was not computed because, the barometer being out of order, its indications were not reliable.

and in places form cavities of such volume that they absorb all the waters that flow from the slopes of this long valley. It is true that these disadvantages may be avoided by running over the argillaceous deposits at the sides, but even thus it will be necessary to cross the unstable strata for lengths totaling perhaps 6 000 meters.

"I believe the preceding indications are sufficient to enable the chief engineer to know what reconnaissances should be made in order to obtain the necessary data for deciding on and laying out the route.

"I will only add that, having had the opportunity to compare frequently the oscillations of the barometer in Vera Cruz with the simultaneous ones of another instrument in a different place, I have observed that the meteorological disturbances were not equally recorded by both instruments.

"The sinuosities and configuration of the country, the relation of different places in the valleys of the streams, make unnoticeable the small variations that may be seen in their full intensity at a place as open as Vera Cruz. This circumstance has given me, for the same place, altitudes that vary by more than 30 meters, and for this reason I believe it is necessary, hereafter, to try to diminish this cause of error.

"It may be advisable to place barometers for comparison in three different places, so as to compare the observations made in three different zones. The one at Vera Cruz would be used as a reference for the observations from the coast to the line from Paso del Toro in the valley of Actopan to San Juan de la Punta and Trapiche de Mesa. That at Orizaba would be used from this line to the crest of the range, and that of Mexico (or perhaps that of Puebla would be best, as it is a central point of the region) would provide the data for the computations of the central plateau.

"In this way the barometer, which is a meteorological rather than a mathematical instrument, would probably approach the former more nearly, because the non-computable variations which are due to atmospheric phenomena would be in part eliminated.

"I close this brief description of the local data because the scientific facts are all available to the Chief Engineer.

"ORIZABA, JANUARY 9, 1858." "P. ALMAZAN."

In 1864, Sr. Almazan was employed on construction work under Capt. Talcott.

In a letter written by Sr. Escandon to Capt. Talcott, dated Paris, 1st September, 1864, occurs the following passage:

"What you say concerning the right of way agrees with what I wrote you myself on this subject in my last letter. I think it would be well for you to withdraw altogether Mr. Almazan from the works now entrusted to him, and to set him with Mr. Merino to do the needful for securing the lands required by the line, which may be done now, if properly managed, with very little and in most cases with no expense at all. Any purchase of lands or agreements will be signed in my name by Mr. Elgnore, my attorney.

"ANTONIO ESCANDON."

By referring to Table 1, it will be noted that the cost of general management, real estate, land damages, etc., is not given, as there were no data for estimating these items.

APPENDIX C

Letters from Mr. William R. Eastman,* Transitman on the Original Surveyed Line for the Maltrata Incline.

"I have read with great interest the report of Capt. Andrew Talcott regarding the location of the Mexico and Pacific Railroad in 1858. I was one of the engineering party brought by Capt. Talcott from the United States, and landed with them at Vera Cruz on January 4th of that year. I was in charge of transit work for one of the field parties, and, in that capacity, ran the experimental line around the Maltrata Valley in July following. In searching for a way from the City of Orizaba to the high table-land, involving a rise of 4 000 ft., within a distance of about 16 miles in a direct line, the ascent at Maltrata was not the first to be tried. At that point there was no wagon road, but, instead, there was an excellent path for horses and pack trains reaching the summit by numerous zigzags. All wheeled vehicles, however, including the daily stages to and from the Capital, were obliged to climb the mountain by the *"camino real"*, the broad national highway which led up through Aculcingo, some 20 miles to the south. As this route had been chosen for the wagon road, the obvious presumption was in its favor, and the pass at Aculcingo was first examined.

"This was done in February with great thoroughness by two field parties setting out from a common point on a level shelf more than half way up the slope and working thence in opposite directions, one up and the other down. Neither party succeeded in making a satisfactory connection, either with the summit or with the valley below. The result was also disappointing with regard to distance and probable cost of construction, and the attempt to locate at this point was definitely abandoned.

"Before the mountain problem was again taken up, in the following July, there had been a diligent search for a better route, and it was found that the pass at Maltrata offered certain positive advantages.

"In going by Aculcingo the stage road made a considerable detour to the south. This elbow would be cut off and the distances to Mexico materially shortened by going up at Maltrata. Besides, there was, on the north side of the Maltrata Valley, a mountain wall in the form of a buttress or spur jutting out squarely to the east from the summit of the pass and, at a distance of 5 or 6 miles, turning north, bounding from that point a transverse valley parallel with the main crest of the table-land.

"The sides of this great mountain spur, lying directly along the general course which we desired to follow, afforded abundant space for prolonging or shortening a railroad line so as to fit the particular grade which might be taken as a maximum. Capt. Talcott, in his report, states very clearly his views respecting a maximum grade, and the topography of Maltrata suited his purpose.

"My party began at the summit at Boca del Monte to cut a line to the valley, which was in full view about 2 000 ft. below. We could make no use whatever of the steep zigzag trail. My instructions were

* Now living in Albany, N. Y.

to set the transit at a depression of about 4 ft. in the hundred and to follow the mountain side wherever the line might carry me. Progress was slow. Three or four men were required to cut an opening through the dense growth of small trees, bushes, and vines, so as to permit a sight from one angle to the next and to allow measurements with the chain. A leveler accompanied the party to note and correct the grade.

"Twice it was necessary to triangulate across abrupt ravines. After some 3 weeks of difficult work we came out on the floor of the valley with field notes for about 11 miles of line, substantially the same, at least in general outline, as that on which the road was built, and which is still shown by the railroad in a printed diagram on the time-tables of the company.

"When the maximum grade for such an incline was determined there could scarcely have been a better location for the railroad ascent to the table-land.

"WILLIAM R. EASTMAN."

"ALBANY, N. Y., MARCH 6TH, 1915."

THE SURVEY OF A ROUTE FOR THE MEXICAN RAILWAY.
BY WILLIAM R. EASTMAN.

"The Mexican Railway, connecting the City of Mexico with Vera Cruz, was opened for public use on January 1st, 1873. The completion of this line between the capital and the nearest and most important seaport was recognized as an event of national importance, and the President of the Republic, Lerdo de Tejada, led the public rejoicings. The road was 264 miles long, had been built at great cost, and represented the planning, working, and vexatious delays of at least 20 years. M. Romero* places the extent of time required at 36 years. From him we learn that a concession for a railroad to Vera Cruz was granted in 1837 and another in 1842. Notwithstanding large appropriations made by the Government, only 11½ miles were built up to November, 1850. At the time of the United States' invasion, in 1847, there were no railroads.

"*The First Railroad.*—The first 15 miles were built from Vera Cruz through Tejeria to the small village of San Juan. In 1858, cars on this road were drawn by a locomotive made in Belgium. In 1854, a short experimental railway, a sort of miniature model of a railroad, was set up in the Valley of Mexico, running out about 3 miles to the suburb of Guadalupe, where was a famous shrine of the Virgin to which frequent pilgrimages were made by all classes of people. This road was wholly of American construction, the rails and other equipment having been hauled 260 miles from the coast. The locomotive was built in the shops at Paterson, N. J., and brought up in detached pieces which were put together by American mechanics. This little road was convenient and popular.

"In 1857, a new concession for a railroad to the coast was obtained from the Mexican Congress by Don Antonio Escandon, a wealthy owner of mines and factories, who paid $1 000 000 into the national treasury and at once entered upon the undertaking with an earnestness worthy of his purpose.

* See his article in the *International Review* of November, 1882, Vol. 13, p. 480.

"*A Mountain to be Climbed.*—The route was evidently difficult, because there was a mountain which must be climbed. The broad table-land of that part of Mexico is, in round numbers, 8 000 ft. higher than sea level. This great elevation is reached in the first 100 miles from the coast. If the slope of the land were uniform and unbroken, an average rise of 80 ft. for each mile, while troublesome, might not be thought a serious obstacle; but the ascent is neither even nor uninterrupted. Starting off with an easy rise, the way gradually grows steeper and steeper. It takes the surveyor by surprise, when, on ground that looks to be almost level, his instruments tell him that he is 40, and then 50, and then 60, ft. higher at the end of a mile than he was at the beginning. At 95 miles, he has risen to 5 500 ft. Then, suddenly, in the distance of 5 or 6 miles, as the wagon road runs, the mountain has lifted itself 2 500 ft. higher still, up to the *cumbres* or sharp edge of the table-land which stretches away in a nearly level plain for 400 miles. This abrupt mountain wall was the railroad problem.

"*Ravines to be Crossed.*—There were also difficulties from deep and steep ravines or *barrancas* which cut across the path. One in particular, the Barranca de Metlac, hid a rushing stream 300 ft. below the surface of the surrounding fields. There was also a line of little hills, the Chiquihuites, standing as a barrier directly across the line of approach. Such were some of the natural obstacles, and it was evident that the best professional advice would be essential to success.

"*An American Engineer and his Party.*—This help was secured by the engagement of an eminent and experienced American engineer, Capt. Andrew Talcott. He was a graduate of West Point, and had rendered conspicuous service in the United States army for 20 years. During that time he had been engaged on such works as the fortifying of Hampton Roads, the building of Fort Hamilton, in New York Harbor, the work at Fort Adams, in Rhode Island, and the improvements of the Upper Hudson River. Resigning his army commission, he had been in demand for boundary surveys in Maine, Michigan, and Iowa, and had been chief engineer of two important railroad systems. He was well fitted by training and experience for this new task.

"A surveying party of some thirty men was at once recruited in the neighborhood of New York, several of them being taken from the staff of the Croton Water-Works and others from the Pennsylvania and Reading Railroads. The chief assistants were M. E. Lyons, of Reading, Pa., and R. B. Gorsuch, of New York, the latter having already had experience in Mexico in connection with the building of the experimental railroad to Guadalupe. Camp equipment, instruments, etc., were shipped from New York.

"The main party sailed by steamer from New Orleans, on January 1st, 1858, and landed at Vera Cruz 4 days later. A camp was immediately established at Tejeria, 9 miles out from the city, and the working parties were organized. These were three in number, a headquarters party, to explore the country on horseback, and two field parties, each with transit and level, prepared to do exact work and keep careful records. In view of the uncertain character of strangers who might be abroad, the camps were always guarded by a sentry at night, and by day each American wore a revolver in his belt.

"Roads and Routes of Travel.—At that time, in Mexico, as in our own colonial days, land travel, if not done on foot, was chiefly on horseback. Merchandise was packed on mules. Wheeled vehicles, except in the cities, were few. Although there were trails and bridle paths in every direction, there were no roads possible for carriages except the one thoroughfare, the *camino real,* from one large city to the next. From Vera Cruz inland there were two such highways. One was by way of Jalapa, mounting the table-land on the north side of Mount Perote, beyond the great snow peak of Orizaba. This route was chosen by General Scott with the American army in 1847. The other road, somewhat more direct, passed through the City of Orizaba, climbed the mountain pass at Aculcingo to the south of the snow peak, and joined the Jalapa road at San Marcos, many miles to the west, leading on thence to Puebla and Mexico. This was the route taken by Cortez and his Spaniards. It was the regular stage route in 1858, and was adopted as the base of the survey. In many respects this was a remarkable road, built probably by the Spaniards 200 or, perhaps, 300 years ago. The location of this broad highway through a mountain country showed great skill in the builders. The massive, arched stone bridges were still intact, and as strong as when first built. There were in many places the remains of a stone pavement; but years or centuries of neglect and spoliation had left only scattered blocks of granite which were more of a hindrance than a help to passage. Along this national road, mule trains with packs of merchandise were constantly passing, up and down, but almost the only wheeled vehicle that used the road was the *diligencia* or stage coach which passed daily in both directions.

"The journey from the coast to the capital required 3 days. At Vera Cruz the coach—one of the familiar type which we know as a Concord coach—was placed on a platform car and went by train 9 miles to Tejeria. At that point horses were attached. There were never less than six horses and, on the steeper grades, eight and ten were often used. Relays were taken every 10 miles and, where the going was good, the team was driven at a gallop. The first day's trip was 82 miles to Orizaba, arriving in time for dinner, a quiet evening, and a part of a night's rest. Starting again before daylight, a distance of more than 90 miles to Puebla was made on the second day. The third day's ride of about 80 miles, passing over an elevation of 10 500 ft. above the sea and thence running rapidly down, brought the tired passengers into Mexico in the afternoon.

"Robbers on the Road.—The journey was tedious enough, but the magnificence of the scenery in the mountain passes was to many travelers no slight compensation. The trip was also subject to some thrilling adventures. The road, especially that part of it between Orizaba and Puebla, was infested with bands of robbers. It was the common daily experience of stage passengers to be stopped once or twice in the early morning and invited, with profuse apologies but at the point of a pistol, kindly to alight from the coach, while three or four men coolly proceeded to possess themselves of money or any valuables that might be found on the persons of the travelers or concealed under the cushions. Articles of clothing, such as hats, coats, and shoes, were often taken from the wearers, and silk dresses

were sometimes stripped from women. If so fortunate as to find a priest among the passengers, the bandits would persuade him also to contribute by holding a pistol at his head until he pronounced a full absolution for the crime.

"The leaders of these robber parties were often sons of wealthy landowners who found life dull on the *hacienda* and led these forays for the mere excitement or the fun of doing it. Passengers, on the other hand, went prepared to pay a little toll, considering it a custom of the country, and carried only a few silver dollars and an old silver watch, and wore their old clothes when compelled to travel by diligence. The American surveying party, whether in its own camps or at its work, was not in any way molested. In September, 1858, however, when the preliminary survey was completed, a party of nine Americans found themselves paid off at the City of Mexico and were unable to obtain New York funds, except at a discount of 15 per cent. They therefore decided to engage the coach for themselves and, being well armed, to carry some $3 000 in coin to the coast. On the second day out, they were twice challenged in the usual way by robbers, and a lively fusillade followed in each instance. No one of the American party was touched, but the woodwork of the coach showed more than one bullet hole. One of the assailants was left dead by the roadside and two others were afterward known to have died from wounds received.*

"A surprising sequence of the above encounter was the sad fate of a Mexican who was traveling in the opposite direction on that unlucky day, and was alone in the coach when, along in the afternoon, it reached the spot where the American engineers had been in the morning. This solitary traveler, who had never heard of the engineers, was taken out by a band of ten men armed to the teeth, was stripped to his underclothes, tied to a tree and lashed without mercy. This was Mexican retribution.

"*Disturbed Conditions.*—The work of the two field parties, begun early in the year, had not continued 2 months before it became evident that the disturbed political and military conditions must seriously embarrass their work. Comonfort was President, and Zuloaga was contesting his claim. Detachments of troops from one side or the other were marching back and forth over the road, and in a small way were fortifying ground here and there along the line. Now and then the sound of cannon and volleys of musketry was heard. There was no very serious clash of arms, but there was just enough of the form of fighting to be annoying to peaceable surveyors. Consequently, the force was reduced, one field party was kept, and the others returned home. The remaining party then began in earnest to examine the most critical point on the line, the abrupt ascent of the *cumbres*.

"*A Choice of Mountain Passes.*—The stage route climbed the mountain by the pass at Aculcingo by a series of ten or twelve extended zigzags. A railroad could hardly do that. After one height was reached, there was another beyond it, and the attempted line of survey became hopelessly involved in a very tangle of hills. A month was

* A notice of this affair may be found by the curious in *Harper's Weekly* for October 23d, 1858, at page 679, under the heading of "Mexico; A Band of Robbers Punished".

spent in trying the possibilities of the ground, and the result was failure. Then the scouting party reported that a few miles to the north was another pass up from Maltrata, and, on the further side of it, a very long mountain spur thrust out for miles into the lower country, a kind of buttress to the table-land. Thither the party turned. They found no carriage road in the Maltrata Pass and the zigzag turns for horses and mule trains were even more numerous than at Aculcingo, but hope was fixed on that prolonged spur of the mountain the sides of which towered half a mile above the village and were as yet unexplored and covered with low trees and tangled brush. After climbing up the path to Boca del Monte, the 'mouth of the mountain', which stands at an elevation of 7 922 ft., the transit was set at a downward gradient of 200 ft. to the mile, and, with only this as a guide, the mountain side was explored. No account was taken of curves, bridges, or tunnels. The chopping out of the path was slow. Straight lines and their angles were carefully measured and noted. The leveling instrument was close behind. Another full month was spent creeping farther and farther along.

"At one point, now called the 'Devil's Balcony', the cliff is so precipitous that it seemed to hang above the streets of Maltrata Village, 2 000 ft. below. Winding on and on, the point of the spur was turned, and a transverse valley to the left was entered. At the end of that came another turn on a hillside to the right and, at some distance farther, another and another turn, until the line drawn on paper resembled the outline of a boot with the leg resting along the valley. At last, after 11 miles of sharp descent, the low level of the village was successfully reached; but there was more of it to come. The water drainage of the valley is through a narrow gorge, so wild that the local name for it is the *Barranca de Infiernillos*, or, in English, 'The Ravine of Little Hell'. Down this rocky gorge the line goes plunging on, turning and twisting again, until at last, in the Valley of Encinal, it comes out into the midst of smooth fields and 10 miles of a straight course brings the line to Orizaba. In 18½ miles, the descent is 3 000 ft. The average of that is 165 ft. to the mile, but many miles are on a grade of 200 ft. or even more. This route has now been in use for 40 years. The locomotives are of the twin, Mogul type, built by Fairlie, each with two boilers, which alternate in supplying steam for the desperate pull.

"*Across the Deepest Gorge.*—The second problem was the crossing of the Barranca de Metlac. As a straight line across was only 1 400 ft., it was a challenge to the engineer to throw a suspension bridge over it, or at least a tubular or cantilever structure with high piers and an enormous span; but the first cost of such a work would also be enormous, and the cost of maintenance very great, and neither of those things was done. Perhaps, if the steel construction of high piers had been as well understood 50 years ago as it is to-day, the straight line might have been secured; but, instead of that, the line, crossing the edge of the ravine, runs down along the inside bank on a narrow shelf for a mile or more up stream until it reaches a broader part of the ravine and then turns across on an almost semicircular bridge, about 100 ft. above the water, and goes back by a similar shelf on the farther side until it reaches the top again and continues on its way.

"The third point of difficulty at the Chiquihuite is met by a considerable detour away from the line of the highway, the railroad striking the side of the hill and rising until it joins the carriage road again, crosses it and passes at once by a high bridge to the farther side of the Atoyac River.

"Thus, step by step, each problem was successfully solved, and in September, after a little more than 8 months in the country, the party returned to New York, the line of survey was plotted, and the report made.

"*Further Delay and Final Success.*—For a long time, nothing more was done. A new grant from the Government was made in 1861. The French Army entered Mexico in 1862. To facilitate their movements they contracted with Escandon to build portions of the road. It was extended over the lower, open country to Paso del Macho, 48 miles from Vera Cruz. It was also carried from Mexico east to Puebla. During this foreign régime, 133 miles were constructed. A still more liberal contract was made with the Republican Government in 1867, and another in 1868. The cost of building was found to be unusual and extreme. Incredible as it may seem, the Government insisted that the road should be built from both terminals simultaneously, making it necessary to haul heavy material, machinery, and equipment hundreds of miles over rough mountain roads in order to build back from the capital. The work of construction of the mountain division, still under the supervision of Capt. Talcott, was taken up in earnest in 1864; but Escandon was compelled to seek outside pecuniary help, which he found in England, and it was an English company which finished the road in 1872—the first railroad in Mexico.

"In spite of its great cost, the need of the railroad has been so great that on the $46 000 000 invested good profits have been paid out of the heavy charges, at least up to within the past year. The road is under English management, and the impression is common that the English built it. The fact is that the survey, the location, and the plan of construction were American throughout.

"From the character of the road it will be seen how easily it can be obstructed by acts of war, by the destruction of bridges and blocking of tunnels; but let us hope that this will never be done. The road is itself a triumph over natural obstacles; it ought not to be ruined by human passions.

"ALBANY, N. Y., JUNE 19TH, 1914."

Mr. Eastman also states that in addition to the members of the corps of engineers given on page 1550, there were several members who came directly to Vera Cruz from New York on another vessel. Three members of the original survey party were killed in the Civil War: Maj. Sidney Coolidge, 16th Regiment, U. S. A., at Chickamauga; Maj. Phillip J. Kearney, 11th New Jersey, at Gettysburg; and Lt. Col. Howard Carroll, 101st New York, at Antietam.

APPENDIX D

Construction Operations, 1861–64, French Occupation.

The unstable conditions existing in Mexico at the time of the presentation of Capt. Talcott's report, which prevented for the time being the construction of the proposed railroad, have already been noted. Under date of Tacubaya, May 19th, 1859, Don Manuel Escandon wrote Capt. Talcott:

"I have set my shoulder to the wheel, and have no doubt of procuring the formation of a Mexican and Puebla Company, to commence at once the works between these two cities, crossing by the Llanos de Apam, which line later on would be continued from Puebla to Orizaba and thence to Vera Cruz."

The question of a joint intervention in Mexican affairs by the European powers of Great Britain, France, Spain, and Prussia was mooted in 1860, and on December 14th, 1861, a Spanish fleet appeared before Vera Cruz, which was at once occupied by the Spanish troops under General Prim. The French arrived soon after, and in September, 1862, more French troops arrived. In view of the unhealthiness of Vera Cruz, the convention of Soledad was concluded with the Mexican Government, permitting the foreign troops to advance to Orizaba.

No construction work was done by Señor Antonio Escandon under the grant of May 31st, 1857, and on April 5th, 1861, he obtained a new grant from the Mexican Government which materially modified the provisions of the former one.

Capt. Talcott received a call to return to Mexico in May, 1861, with which he was unable to comply, and suggested the employment meantime of Mr. M. E. Lyons, his former Principal Assistant, which was accordingly done, and Capt. Talcott did not return to Mexico until March 1st, 1862, having left Charleston, S. C., on January 9th, 1862, on the blockade runner *Carolina* for Nassau, and thence *via* Havana to Vera Cruz, where on arrival he resumed his duties in connection with the construction of the Mexico and Pacific Railroad.

The French, on their arrival in Mexico, found no railway, except the few miles of track operated by mules from Vera Cruz, which was used to transport passengers and their baggage about 9 miles to Tejeria, from which point transportation to the interior was over old Spanish highways that at many points were almost impassable during the rainy season; and their efforts were immediately directed toward the construction of a railway across the *Tierra Caliente,* in which they seem to have had the co-operation of the "Escandons", for entries found in Capt. Talcott's diary for February, 1863, indicate that, as

the representative of Antonio Escandon, he was supervising work in progress in Soledad.

It appears, therefore, that the demand for better facilities for transportation by the French Army was responsible for the construction of what is now known as the "Mexican Railway" from Vera Cruz to Soledad, where it crosses the Jamapa River, and practically determined the Orizaba Route for the Imperial Mexican Railway Company in 1864.

It was not until after the arrival of Emperor Maximilian (Vera Cruz, May 28th, and City of Mexico, June 19th, 1864) that Antonio Escandon made rapid progress in his negotiations with English capitalists which finally resulted in a contract, dated August 19th, 1864, between "The Imperial Railway Company, Limited", and Smith, Knight and Company, Limited, by which the last named Company undertook to

"complete and construct a Railway from Vera Cruz to the City of Mexico and a Branch Railway to Puebla, according to the plans, sections, and specifications in that behalf made by Mr. Talcott, one of the Engineers of said Company."

In anticipation of the conclusion of this contract, Don Antonio Escandon had written to Capt. Talcott as follows:

"ANDREW TALCOTT, ESQ.,
Mexico. "PARIS, 31 July, 1864.

"DEAR SIR:—I thank you for the information you give me concerning your operations on the portion of the line near Mexico and am happy to see that Messrs. Almazan, Merino and your son Richard are employed on the same. You must bear in mind, as I told you before, that no rails are to be placed on that part of the line and that you have nothing else to do but to go on with the earthworks without exceeding your estimate of 1858, nor anyhow the amount of $15 000 per month. Any such excess would be a dead loss for me; on the contrary, I would profit by any difference below your said estimates, in conformity with which these works will be reimbursed by the contractors.

"I must renew my observations concerning the settlement of account with the French Government should the question be brought before you. This settlement must be done in strict accordance with the contract made with the French Engineers. That is to say, from the sums advanced must be deducted the amounts received by the French and the customs dues up to Dec. 31, 1864, and those due to the Railway for carriage of the French Army, its baggage, etc. If any difference results against me, I will pay it forthwith in money on 1st January, 1865, and can admit of no settlement made on other terms than these.

"I will besides recommend you most particularly to reserve all my rights against the French Government in consequence of the losses sustained by the Company by cases of *force majeure*, such for instance as that which occurred when W. Lyons was mortally wounded by the

guerillas, who carried off a certain sum of money belonging to the Company and destroyed part of the road. (The illness of W. Lyons, as you know, delayed for some time the progress of the works), besides several other cases which are not present now to my memory.

"The principal injury we sustained was when the guerillas carried off all the workmen on the line with the cash in hand for payment of the same. This is the point that must be principally insisted upon.

"Yours,

"ANTONIO ESCANDON."

After the execution of the contract with Smith, Knight and Company, Don Antonio Escandon wrote a letter to Capt. Talcott, as follows:

"PARIS, August 31, 1864.

"Messrs. Smith, Knight and Co., the constructors, have had the good fortune to secure the services of Mr. Lloyd, a friend of Messrs. Gibbs, who has constructed an important Railway in Peru, where he has resided 10 years. This gentleman, with Mr. Samuel, will leave for Mexico probably by the St. Nazaire Steamer of September. He will remain only a short time there to see what are the materials that he has to purchase in Europe for account of the constructors, after which he will return to England. You must therefore get everything ready for the delivery of the constructed part of the line, which will be made immediately after the arrival of these gentlemen.

"I have asked the French Minister of Public Works to grant me an audience in which I intend to request him to withdraw entirely the French Control in consequence of the formation of the new Company. So I think you will soon be easy on that score.

"THURSDAY, 1st September, 1864.

"After writing what precedes, and at the last hour I receive your favor of the 29th July.

"By what I have already told you, you will see that it is very urgent that you should immediately go over to Vera Cruz to get the Schedule made of all the Stock belonging to the Railway, without distribution even of the light rails, which, by my contract, will be returned to me by the Company.

"My engagement being to deliver the road up to the Paso del Macho I need not tell you that no expense for Surveys, etc., must be made beyond that point.

"ANTONIO ESCANDON."

It is very evident from the foregoing that what is now known as the "Ferrocarril Mexicano" from Vera Cruz *via* Soledad and Camaron to Paso del Macho was built by Don Antonio Escandon under the concession for the "Mexico and Pacific Railroad," for which surveys were made by Capt. Talcott in 1858.

It also shows that this part of the road was built under the control of the French Government, in accordance with an agreement made

with French engineers, and that for this 77 km. of railway the Imperial Mexican Railway Company paid Don Antonio Escandon an agreed price after it had been completed at his cost from Vera Cruz to Paso del Macho.

It is not unlikely that this section of railroad, at the time of formation of the Imperial Mexican Railway in 1864, was in a deteriorated condition and required extensive repairs, which is no doubt the meaning of the word "refections" used in the following letter:

"Mexico, October 17th, 1865.

"Private and Confidential.

"Col. Andrew Talcott,

"Dear Sir: As I understand that you are going over the line to Vera Cruz, I have to request you to give your attention to the refections which have been made by Mr. Pogenstecker under Mr. Lloyd's orders in pursuance of my contract with Mr. Lloyd.

"I have already paid $200 038.57 for these works, and I should be much obliged to you to report to me what has been done and how much more remains to be done.

"With respect to that part of the refections which has been completed I wish to know how much the same work would have cost under the conditions in which the works of construction are paid to Smith, Knight and Company.

"And as the work now executed must be submitted to your approval before being accepted by the Imperial Company, I should be much obliged to you to tell me how the refections have been carried out. Do you consider it necessary that the remainder should be completed on so expensive a scale; and how much do you think it should cost, according to Smith, Knight's contract with the Imperial Company?

"I am, dear Sir,

"Faithfully yours,

"Antonio Escandon."

It also appears that Don Antonio Escandon constructed, in part at least, the line from the City of Mexico to Guadalupe and east of Guadalupe to the Llanos de Apam, for which work he was paid by Smith, Knight and Company, on the basis of Capt. Talcott's original estimate of its cost, for the construction of this part of the line was included in the Company's contract to build the railroad from Paso del Macho to the City of Mexico.

APPENDIX E

CONSTRUCTION OPERATIONS, 1864–66, UNDER EMPEROR MAXIMILIAN.

Immediately after the organization of the Imperial Mexican Railway, August 19th, 1864, extensive measures for the speedy construction of the unfinished portion of the railroad were begun, although the transfer of the concession held by Don Antonio Escandon was not approved by the Emperor Maximilian until January 26th, 1865, which approval fixed the time of completion of the entire line by April 30th, 1869. The chief contractors, Messrs. Smith, Knight and Company, were the builders of the Chilian railroad from Valparaiso to Santiago, and came from that country to Mexico. They had their own staff of engineers, Mr. S. Samuel, Chief Engineer in London, England, and Mr. William Lloyd, Chief Engineer in Mexico, Messrs. William Cross Buchanan and Alister Fraser, Division Engineers, Mr. Richard Ingalls, Superintendent, and others, all Englishmen. On the staff of Capt. Andrew Talcott, were his son, Mr. Richard H. Talcott, now of Albany, N. Y., Mr. T. M. R. Talcott, now of Richmond, Va., Sebastian Wimmer, M. Am. Soc. C. E., now of Albany, Minn., the late Gen. W. H. Stevens, formerly on the staff of Gen. R. E. Lee, Col. H. T. Douglas, now of New York City, and other American engineers.

Many of the latter had served in the Confederate Army during the Civil War (United States), and had secured positions in Mexico at the close of that war, in April, 1865. The chief contractors, Smith, Knight and Company, were afterward succeeded by George B. Crawley and Company. Mr. Sebastian Wimmer, after his arrival in Mexico, was placed in charge of the construction of the seven upper sections of the Maltrata Incline (so-called) on April 26th, 1865, and some time after was placed in charge of additional sections, lower down, near the Town of Maltrata. While in charge of this work he made a number of modifications and changes in the alignment which greatly improved it.

The following excerpt from Mr. Wimmer's diary is of more than ordinary historical interest:

"*Saturday, April 29, 1865.*—Emperor Maximilian arrived at Maltrata at 12 o'clock noon. I was introduced to him, as well as the other engineers, and had quite a chat with him. He wanted to know how I, a German, from Munich, Bavaria, Germany, came to be associated with the English party of engineers engaged on the Imperial Mexican Railway. I explained that I was a citizen of the United States, a practicing civil engineer for the past fourteen years (1851-1865), having arrived in New York city, June 2d, 1851, and when civil engineers from the United States were required for service in Mexico, I applied for a position on this railroad and then received an appointment on this important work.

"He told me that he well remembered Abbot Boniface Wimmer, my uncle (with whom I arrived in New York as above), and favored his project to establish in America 'The Benedictine Order'.

"We all had a fine dinner in the open verandah of the chief contractor's house (Smith, Knight & Co.), a native Indian brass band played in the open patio. Leo Thun, Major General of the Austrian troops, quartered at Puebla, was one of his party, also his private secretary Elvin, Minister Ramista, Prince Wittkenstein, a Russian officer, and others of his escort. Others present were Wm. Lloyd, Chief Engineer of Smith, Knight & Co., Mr. Richard Ingalls, Superintendent, Engineers Richard H. Talcott, Fred. Simons, my friend Rudolph Wieser, Mr. Wm. H. Burr, Dr. Manifred, Wm. Cross Buchanan, John Quinn, and others.

"A messenger from Orizaba arrived with a telegram for the Emperor, announcing that President Lincoln of the United States was killed on April 14th, 1865, in Ford's Theater, Washington, and Secretary William H. Seward and Fred'k. Seward wounded, by John Wilkes Booth, the assassin. This news at once stopped the dinner, as the Emperor wanted to put himself in telegraphic communication, and Orizaba was the nearest point, some 15 miles away. We all escorted the Emperor to Orizaba that afternoon."

Also this excerpt:

"*Monday, December 25, 1865.*—At Orizaba. Christmas Day. Hot and dry. Attended midnight high mass with Davison. At 8 A. M. all we engineers rode about 3 miles down toward Cordoba, to escort Empress Carlotta to Orizaba, who was returning from Yucatan to the City of Mexico. She arrived about 11 o'clock, seated in an open carriage with a court lady, and accompanied by a large number of French Zouaves on horseback, several hundred, plowing through six inches of dusty road, causing such a dust that we could not see one another, and covering the poor Empress and her lady companion so that it was awful to behold. They escorted her to the Cathedral for a grand reception by the authorities and thence was to receive us, but, being exhausted, she went to Bringas residence to rest and to receive us the next day.

"*Tuesday, December 26, 1865.*—Hot weather. I called with Ed. Melgar on Col. Rodrigues to arrange about our introduction to the Empress. She received us at Bringas. General Uraga (one leg lost in war lately) acted as introducer. Richard Ingalls was our spokesman. Richard H. Talcott and myself, Mason Peek, Maynadier, W. S. Davison, Wm. B. Cooper, and Slate were introduced. She spoke Spanish fluently, but she soon discovered that most of us were rather embarrassed and preferred English, and when Mr. Ingalls was not aware that the Empress spoke English, she answered that it was the second language she had learned and loved to speak it. We thence got along very well, and when Mr. Ingalls invited her to come on her way up to the city of Mexico *via* the *Las Cumbres* work, she replied that she loved to accept the invitation, as the Emperor had already told her of his delight of having been there last spring, but she had already received a telegram from the Emperor, who was in Puebla, to

come on at once, without further delay, and as a dutiful wife, 'I must obey' and thus be unable at this time to see for herself how far the contractors of the railroad had proceeded toward a soon completion, for you have seen what a terrible thing it is to travel in this country, and so exhausting, and asked us to hurry the work to completion."

On July 8th, 1866, the Empress Carlotta left Mexico on a visit to Napoleon, Emperor of France, to arrange Mexican affairs, never to return. Her husband, the Emperor Maximilian, as is well known, was executed June 19th, 1867, at Queretaro.

Mr. Wimmer's diary contains a daily minute description of every happening during his connection with this work, 1865-1867, affording unlimited material for the historian, but lack of space prevents giving any more excerpts.

His name is indelibly associated with the Mexican Railway by having one of the bridges on the Maltrata Incline named after him, perhaps the only record where a civil engineer has thus been honored. This bridge is shown by Fig. 8.

Another official prominently connected with the Imperial Mexican Railway was Mr. Thomas Braniff, formerly of Staten Island, New York. He had been with Gen. Meigs in Peru, on the Lima and Oroyo Railroad over the Andes.

Later, Mr. Braniff became General Manager of the Mexican Railway, and also the owner of a large cotton factory at Ingenio, a short distance west of Orizaba, accumulating a large fortune and becoming an influential resident of Mexico.

In the spring of 1866, the Imperial Mexican Railway Company became financially embarrassed, and Capt. Talcott had to obtain funds from Barron, Forbes and Company, of the City of Mexico, to meet engineering expenses in carrying out instructions he had received to prepare and submit final estimates of the work done so far by Smith, Knight and Company and their successors George B. Crawley and Company.

At that time the railway was in operation between Vera Cruz and Paso del Macho, 48 miles, and was opened to Apizaco, 87 miles from the City of Mexico, for freight service, January 21st, 1867.

APPENDIX F

Construction Operations, 1867–73, Under Republic of Mexico.

Capt. Talcott severed his connection with the Imperial Mexican Railway on February 10th, 1867, he holding at the time the position of Joint Engineer in conjunction with Mr. James Samuel, of London, England. Leaving the City of Mexico, February 23d, 1867, he arrived in New York City on April 5th, 1867. During his connection with this railway he had constructed 135 miles of road.

After the downfall of Maximilian and the withdrawal of the French Army, Señor Escandon applied to the re-established Government of the Republic, to revalidate his concession, and, notwithstanding he had been a staunch supporter of the French and of the enemies of the Republic, the Mexican Government, on November 27th, 1867, made a new contract with him, under more liberal terms than his former grant. This contract was again modified on November 11th, 1868, and the railroad was finally finished on December 31st, 1872, under the Escandon grant, 16 years after his first contract was made, and 36 years from the date of the first concession. It was formally inaugurated on January 1st, 1873, by President Sebastian Lerdo de Tejada.

The Puebla Branch was finished on September 16th, 1869, the main line to Paso del Macho, in 1864, to Atoyac, January 9th, 1871, to Cordoba, August 22d, 1871, to Fortin, December 8th, 1871, and to Orizaba, September 5th, 1872.

A great deal of misinformation has been published about the Mexican Government requirement of hauling rails and equipment overland. This requirement was a practical necessity, and was dictated by common sense, as the construction work on the table-land was comparatively light and the grading between the City of Mexico, Apizaco, and Puebla was finished 5 or 6 years before that of the sections lying farther toward Vera Cruz, between Boca del Monte and Paso del Macho, where the heaviest work on the railway occurs.

This is particularly emphasized by the fact that it was proposed originally to form a company to build first a railroad between Puebla and the City of Mexico, by way of the Llanos de Apam, which line, it was believed, would become so lucrative that it would soon be continued to Orizaba and thence to Vera Cruz. Had not the French invasion occurred, this would have been the procedure of construction, although the original plan was partly carried out, with this modification.

DISCUSSION

Mr. Mathewson.

T. K. MATHEWSON,* M. AM. SOC. C. E. (by letter).—The wealth of information, both historical and technical, contained in Mr. Low's paper will be a revelation to most engineers, even to those who have often passed over the Mexican Railway. That it was located, and to a great extent built, by American engineers will be news to those who have always heard it spoken of in Mexico as "The Queen's Own". The road has always enjoyed an enviable reputation for safety, in spite of the sharp curves and steep grades.

The Maltrata Incline, with its 4% grades and great curvature, would seem to offer an attractive field for electrification. The nearness of water-power and the absence of snow and sleet make the conditions favorable. It is the writer's belief that such a change in motive power has been considered by the company. It is his understanding that a masonry flume was built in one of the streams, possibly the Atoyac, in which to make measurements of the flow, under the direction of the late George Foote, who was at one time Chief Engineer of the road. Possibly the articulated Fairlie engines, with their short wheel base, make electrification less attractive. This may well be the case, as fuel oil from the Tuxpam oil fields, near-by, is now used in place of coal briquettes from England. Details of these engines would be interesting, as they are one of the unusual features of the line.

The description and history of this interesting railway could hardly be more complete, in spite of the fact that the disturbed condition of Mexico has made communication with the country very difficult at this time. The paper will be especially interesting to those who know and love Mexico.

Mr. Douglas.

H. T. DOUGLAS,† ESQ.—Mr. Low is to be congratulated on the complete description of the Mexico and Pacific Railroad, the location and construction of which furnish one of the best examples of bold engineering—especially from Tejeria to Boca del Monte—to be found on this continent.

The writer had the honor to serve under Col. Talcott in locating the line from Paso del Macho to the Rio Metlac, and in constructing "The Division of the Boot" (La Bota) in the center of which the Village of Maltrata is situated. He also served under Col. Talcott in Virginia.

Col. Talcott belonged to a period which furnished some of the most distinguished engineers to America—the pioneers who blazed the way. Among them were Messrs. Charles B. Fisk, Charles Ellett, and Benjamin H. Latrobe, and Colonels Claudius Crozet (a soldier of Napoleon's great army), C. F. M. Garnett, and Walter Gwynne—a

* Tucson, Ariz.

† New York City.

Mr. Douglas. galaxy the like of which is rarely found. In this company of great engineers, Col. Talcott, because of his high professional attainments and exalted character, measured up to the highest mark, and the writer recalls his service under him with the greatest pleasure, as it supplied a lesson which has never been forgotten.

Col. Talcott's sons, Charles, Richard, George, and T. M. R. (the latter a Colonel and Aid-de-camp to Gen. Robert E. Lee), all distinguished engineers, were the writer's personal friends and associates; he also recalls his service on this railroad with Messrs. William Cross Buchanan, Sebastian Wimmer, Richard Ingalls, and Dr. Manifred, with much pleasure.

Mr. Ingram. W. T. INGRAM,* ESQ. (by letter).—The writer has read Mr. Low's paper with deep interest. A great many of the data which he has gathered together, it is thought, have never before appeared in print; in fact, the present management of the railway was unaware that such a mass of information was still extant. The paper will prove a valuable addition to the Company's archives, and will be very interesting reading to those engineers who have been directly or indirectly connected with this, or, in fact, with any railway in Mexico.

This railway, opened for public service 43 years ago, is a lasting monument to the skill and energy displayed by the pioneers, and stands to-day a model of railway construction in Mexico.

Not until recent years has there been any serious attempt to improve the grades and alignment to meet the growing traffic, and it has been found that the most that can be done is to reduce the grade on the table-land, that is, from Esperanza to Mexico, from 1½ to 1%, and by building a high-level bridge over the Metlac River to save the expense of operating trains in and out of the ravine.

It is stated that the project of building a high-level bridge was abandoned—or, at least, very strongly influenced—on account of an earthquake which occurred while the project was under consideration; if this is the case, it was most unfortunate that the earthquake should have occurred at such an inopportune moment, for during the writer's long residence of nearly 28 years, spent wholly between the City of Mexico and Vera Cruz, he has never known, nor even heard from "the oldest inhabitant", of any earthquake which would have imperiled a high railway bridge, that is, of course, in the neighborhood of Orizaba. On the table-land he has experienced several severe disturbances, but these are reduced in intensity as the coast is approached; in fact, a severe earthquake in the City of Mexico is barely noticeable in Vera Cruz.

If it was unfortunate that the high-level bridge was not built in 1866; it is still more unfortunate that the Revolution, which commenced

* Res. Engr., Ferrocarril Mexicano, City of Mexico, Mexico.

Mr. Ingram.

in 1910 and still continues, has deferred its construction indefinitely, due to the fact that, after long deliberation, it was considered that a bridge of such magnitude would be very easily destroyed, with, of course, disastrous consequences. Fortunately, the present Metlac Bridge and practically all others have escaped serious damage, but the danger has been ever present for several years past, and very great anxiety has been felt by all concerned; how much more so would this have been the case had the bridge been nearly 350 ft. high?

Some day, of course, the bridge will be built, as the development in and out of the *barranca* is perhaps the most dangerous part of the railway, and mile for mile the most expensive to operate. When this day arrives, it is to be hoped that the Mexican people will have developed into a peaceful and law-abiding nation.

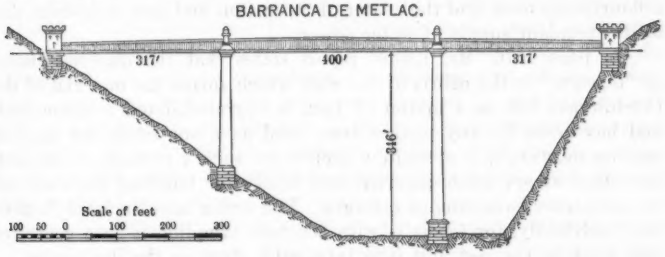

FIG. 11.

Mr. Lyons, in his report, condemned the route *via* Las Vigas and Jalapa, stating that the country was most unfavorable and that all cuttings would be in volcanic rock. His prognostication, however, has not been fulfilled, as the Interoceanic Railway, a narrow-gauge (36-in.) competing line with the Mexican Railway, follows the route which Mr. Lyons considered so unfavorable, and, moreover, the grades do not exceed 2½%, as compared with 4% (both uncompensated) of the Mexican Railway, the maximum curvature on both lines being practically the same, namely, 100 m.

The Interoceanic as it stands to-day is 50 km. longer than the Mexican Railway, but some 9 years ago a line was actually located from Las Vigas *via* Jalapa, to the foot of the mountain, using the same grade, namely 2½%, but compensated with maximum curvature of 200 m. The distance was shortened considerably, but this location involved the construction of an entirely new line for a length of some 125 km., consequently the project is hardly likely to be entertained favorably for some years to come. As a matter of fact, there is less rock on the Interoceanic route; the lava flow from the "Cofre de Perote", which has to be crossed, no doubt on first acquaintance looked very formidable, but its natural fall happens to fit the grade, and

Mr. Ingram.

the cuts and fills are relatively light. As the original scheme was to connect the City of Mexico with Vera Cruz, to a great extent irrespective of the intervening towns, except Puebla, which very rightly has been connected to the main line by a branch, the writer believes that, had the Jalapa route been studied as thoroughly as that of Orizaba, the former would have been selected, due to the more favorable grade.

On the other hand, however, the Orizaba route passes through towns and villages of greater importance and a much more cultivated and productive part of the country; consequently, on the whole, and in the light of after events, the selection of the route of the first railway in Mexico was a happy one. Jalapa is of no commercial importance, it being merely the seat of the State Government, whereas Orizaba is a flourishing town and the center of the cotton and jute industries, due to its abundant supply of water power.

On page 1576, Mr. Lyons' report states that the material known as "tepetate" is the débris of the rock which forms the material of the Cordilleras; but, as a matter of fact, it is consolidated volcanic mud, and has never by any chance been used as a substitute for sand in making mortar; it is absolutely useless for such a purpose, or, in fact, any other except when quarried into blocks for building purposes and for temporary ballasting of railways. The writer uses the word "temporary" advisedly, for tepetate, with constant tamping, is soon converted into mud in the wet and into intolerable dust in the dry season.

Mr. Perez Castro.

L. Perez Castro,* M. Am. Soc. C. E. (by letter).—This paper is very useful to those interested in the history of the leading railways of Mexico. The history of the grants and concessions, as well as of the progress of construction of the Mexican Railway, can be learned from the official reports of the Mexican Government, but very little has been published in reference to the engineering achievements of the pioneers on this wonderful railway. In fact, apart from the papers and reminiscences of the living men of that epoch, it is rather difficult to get extensive information about the matter.

At present, the reports of Capt. Talcott and his assistants have essentially an historical value, as the ideas now prevailing in reference to the location and construction of railways in Mexico are different from those of a quarter of a century or more ago, on account of the dissimilar conditions now obtaining. There are some engineers in Mexico, familiar with the country crossed by the Mexican Railway, who believe that its location could have been improved by following another line, but adhering to the same route south of the "Pico de Orizaba".

At the present time the volume of traffic carried by the railways of Mexico is far greater than that of former years, but, on the other

* City of Mexico, Mexico.

Mr. Perez Castro.

hand, the cost of fuel has increased considerably. A large proportion of the coal has to be imported. Recently, the use of Mexican fuel oil has resulted in great economy in the transportation expenses of these railways, but not enough to determine a change in the criterion relating to the maximum grades, for the price of fuel oil is steadily increasing.

The construction of the Interoceanic Railway, *via* Jalapa, is more in harmony with the actual requirements as to ruling grades, in the descent from the "Mesa Central" (Central Plateau) to the sea-level lands, as its heaviest grades are from 2.5 to 3%, instead of the 4.5% of the Mexican Railway (in both cases without compensation for curvature). The maximum curvature in each is about 12° (20-m. chord), or between 90 and 100 m. of radius. Wherefore, the Interoceanic Railway, in spite of the handicap of its present narrow gauge (0.914 m., or 3 ft.), has secured a greater freight traffic than the Mexican Railway, of standard gauge. It can be estimated that, before the outbreak of the political disturbances in Mexico, 60% of the freight from Vera Cruz to the table-lands was handled by the Interoceanic and the remainder by the Mexican Railway. The passenger movement has always been considerably superior on the latter railway, owing to the greater speed and comfort in making the trip, and also on account of its more attractive scenery.

With the facilities now available in the line of construction, and considering the necessities of an intensive traffic, it is admitted that the maximum grade suitable in the mountainous parts of Mexico, *viz.*, in climbing to the high lands, is 2% compensated for curvature, with maximum curves of 6° and, exceptionally, 8° (191 and 143 m. of radius, respectively, 20-m. chord). With this grade and 6° of sharp curves, a new line has been located between Las Vigas and Vera Cruz, on the Interoceanic Railway, and this will surely be constructed when the contemplated widening of the present narrow gauge takes place. The projected short line between Mexico City and Tampico—which is a pressing necessity—undoubtedly will be realized with such maxima of grade and curvature, notwithstanding the tremendous difficulties to be overcome in descending from the "Mesa Central", whichever route may be selected as suitable for the purpose. The different and numerous surveys have demonstrated that with 2.5% grades, the work would be somewhat simplified, although the prevailing tendency favors the maximum of 2 per cent.

With modern developments in electrification matters, and the use of hydro-electric power—which can be improved to a great extent in the Mexican mountains—the present limitation of grades can be economically increased; but, in the construction of new lines, the tendency at present is to exceed such limitations and use such lines exclusively for passenger and express purposes, like the Mexico-Puebla

Mr. Perez Castro.

line, passing between the snow-capped volcanoes, Popocatepetl and Ixtaccihuatl, and the Mexico-Toluca line, through the "Sierra de las Cruces", the construction of which was being carried out by the Mexico Tramway Company when it was delayed by the political troubles of the country. The maximum grade adopted on these lines is 6%, but on heavy-traffic lines already in existence, such as the Mexican Railway, surely in the near future, hydro-electric energy will be used, resulting in greater economy than that obtained with fuel oil as a substitute for coal.

On the lines in the "Mesa Central", the southerly part of which is essentially hilly, it is now estimated that 1% is the maximum economic grade, compensated, with 6° of greatest curvature, instead of the 1.5% grade largely used hitherto. The section of the Mexican Railway between Mexico City and Boca del Monte reaches in some stretches 1.5%, but surveys have been made with the object of reducing it to 1%, and it is possible that, when the conditions of the country are improved, this work will be started. On the Interoceanic Railway, between Mexico City and Las Vigas, similar surveys have been made for the purpose of making the necessary betterments in location when the road is widened to standard gauge. In the low country, lying between the foot of the mountains and the sea, the reasonable maximum grade is 0.5%, compensated, with maximum curvature of 2% (573-m. radius, 20-m. chord) and eventually 4° (287 m.). Thus has been located the coast line, pending construction, by the National Railways of Mexico, between Vera Cruz, Tampico, and Matamoros, the latter point on the United States border. In the surveys of the line from the Isthmus of Tehuantepec to the Yucatan Peninsula, grades of 1% have been proposed—and higher still in the neighborhood of Campeche—but this should not be approved as it would indicate a bad selection of the route, the land making it easy to keep the limit at 0.5 per cent.

Mr. Talcott.

T. M. R. TALCOTT,* ESQ. (by letter).—When Capt. Talcott assumed the duties of Chief Engineer of the Mexico and Pacific Railroad, in December, 1857, he was in his sixty-first year, and it was deemed desirable that one of his elder sons should accompany him as his personal assistant. For this the writer was to some extent qualified as he had had 18 months of previous training in that capacity on the Ohio and Mississippi Railroad, and had assisted his father in astronomical observations for the State of Virginia.

Some preliminary examinations of the ascent from Vera Cruz to the *cumbres* had been made by Mr. P. Almazan, a Mexican engineer, prior to the arrival of the expedition at Vera Cruz on January 4th, 1858. As Capt. Talcott was anxious to verify the barometrical eleva-

* Richmond, Va.

tions of some of the passes ascertained by Mr. Almazan, without waiting for the delayed transportation, he and the writer left Vera Cruz by diligence on the night of January 10th, and arrived at Orizaba the next afternoon. Mr. Talcott.

Having obtained saddle horses and a competent guide, the party started early on January 12th on the first of the many explorations on horseback in advance of the engineer parties, spending 5 days in the saddle, during which an examination was made of the route of the Diligence Road *via* Aculcingo as far west as Puente Colorado, a summit south of Aculcingo, which Mr. Almazan reported lower than the Aculcingo Pass, but which was found to be higher; the Canada de Regina Pass was also examined, and a route between Orizaba and Cordova which crossed the Barranca de Metlac north of the Diligence Road. The return to Vera Cruz was made by diligence on January 17th, and soon thereafter the engineer parties were fully equipped and in the field.

After a week spent at "Camp Escandon", near Vera Cruz, Capt. Talcott's next start was on horseback with the writer, and a Mexican *mozo* to care for the horses. The writer finds, from the only notebook which he has preserved from that period, that from January 25th to 31st, while on the way to Orizaba, he recorded astronomical and barometrical observations at Soledad, Chiquihuite Summit, and Potrero.

Early in February, Capt. Talcott established his headquarters at Orizaba, where he opened an office to which Mr. Coolidge and his assistants were moved from Camp Escandon; and thereafter hourly readings of the barometer and thermometer were recorded there, for comparison with contemporaneous observations by the surveying parties in order to determine elevations at controlling points along the Orizaba route then being surveyed. Astronomical observations were also made regularly for the rating of the several chronometers.

Capt. Talcott made a number of explorations both east and west of Orizaba during February, and the writer's notebook contains records of repeated observations at Maltrata, and at Aguila and Aculcingo Passes during that month.

Later, when there was fighting at Orizaba, Mr. Coolidge joined the "Liberal" party and was made prisoner by the "Conservadores", which for a time complicated the relations of the engineers with the military authorities of that party. Before that, when challenged by sentinels, the engineers were allowed to pass by saying that they were "American Engineers", but afterward they had to explain to officers at military posts that they were "Railroad Engineers" before being allowed to pass.

When there was no longer doubt of the practicability of the Maltrata route, Capt. Talcott extended his personal explorations west of the *cumbres* into the open country of the plains. On these reconnaissances each successive course by compass was recorded, and its length was

Mr. Talcott.

estimated by the time consumed in traversing it at a steady pace on horseback. In the middle of the day a halt was made in order to get the time by equal altitudes, and the approximate latitude of the halting place by circummeridian altitudes of the sun.

At night, both latitude and longitude were again determined by observations of the stars, thus fixing approximately the geodetic position of two points on each day's journey, from which the latitude and departure of each half day's journey was calculated and used in correcting the approximate scale of estimated distances. From these data the field parties were furnished with rough maps showing the routes traveled and such topographical features as had been sketched *en route*.

On May 25th, Capt. Talcott left Orizaba on horseback, accompanied by the writer and a Mexican *mozo*, and soon thereafter established his headquarters at Puebla. While there, on June 19th, the party had its first experience with an earthquake, but the shock was more severe in the City of Mexico.

On July 12th, according to the diary, the party left by private conveyance for Tlascala "to explore the route from Esperanza to Huamantla and Apam." While on this trip, the writer was left at Nopalucan, Capt. Talcott says, "to take charge of the line commenced by Lyon at Esperanza *via* Nopalucan, etc." This was the line which was finally adopted and built from the Boca del Monte to Apizaco. While the writer was engaged on this line, Capt. Talcott returned to Puebla, and, on July 20th, went thence *via* San Martin to Apam, from which point he made explorations "as far west as Saupauca [Soapayuca], in sight of Lake Texcoco and Otumba."

Starting again from Puebla on July 28th, he says he found the writer's party at Huamantla, and went thence, *via* San Andres to Orizaba, and thence returned to Puebla by August 4th. There the writer rejoined him and went with him to the City of Mexico on the 7th, and found that Don Manuel Escandon was in prison because he had refused to pay a forced loan of $400 000 demanded by the *de facto* government of Mexico. No one was allowed to visit him in prison, and after remaining in the city for a week, Capt. Talcott and the writer returned to Puebla without seeing him.

When the surveys were nearing completion, and the question of a general map was being considered, it occurred to the writer that it would be more complete and satisfactory if the Diligence Road from Puebla to the City of Mexico could be shown on it.

Time was short, and all the regular parties were otherwise engaged, so the writer offered to undertake the work and complete it in one week with such assistance as could be spared, including only Mexicans as rodmen and chainmen.

Mr. Talcott.

Half a day was lost in starting, by reason of an oversight in not getting a written permit from the Alcalde of the city, which led to the arrest of all in the party except the writer.

The first 20 miles to San Martin were not deemed essential, as this part was covered by information previously obtained, and as time was short the party hastened to that place, where the actual survey was commenced the next morning, starting with the elevation which had been ascertained by repeated observations of the barometer on previous trips by diligence to and from the City of Mexico.

From San Martin to Ayotla the distance was measured by chain, courses were taken by compass, elevations determined by level and rod, and as many as possible of the topographical features of the country between the Diligence Road and the line *via* Apam were fixed by triangulation.

On the morning of the sixth day, after passing over an elevation of about 10 200 ft. at Rio Frio, the party was on the shore of Lake Texcoco, the level of which above the sea had already been determined by the survey *via* Apam, and was surprised to find that the elevation of the lake differed only a few feet from that determined by the survey from Vera Cruz.

The dome of the Cathedral in Mexico being in plain view, its distance was determined by triangulation, and also the course of the causeway across Lake Texcoco, which, for the want of more time, was the best that could be done to connect the line with the survey *via* Apam.

After returning to the United States, in October, 1858, the writer remained with Capt. Talcott for several months, rendered him some assistance in the preparation of his report, and accompanied him to Arizona in 1860, during the interval in which he was waiting for his recall to Mexico.

In 1861, when Don Antonio Escandon sent a special messenger through the Federal lines with letters to Capt. Talcott asking his immediate return to Mexico, neither he nor the writer felt that they could leave the service of the State of Virginia in which they were then engaged on river, coast and harbor defenses; and, later, when Capt. Talcott did return to Mexico, the writer was in the Confederate Army, where he remained until April 9th, 1865, when Gen. R. E. Lee, on whose staff he had been serving, surrendered to Gen. U. S. Grant.

In the spring of 1866, when Capt. Talcott was in great need of engineers to replace those who had left, or were about to leave him, for service with the English contractors, the writer returned to Mexico, taking several assistants of his own selection, and succeeded Gen. W. H. Stevens, who had been in charge of construction on the Maltrata Incline as Division Engineer.

Mr. Talcott. During the months which followed, until the following February, when the French army was withdrawn, the chief occupation was measuring up, and preparing estimates for work done, which were the basis of a subsequent settlement with the English contractors.

In conclusion, the writer cannot refrain from saying that, of all the engineers who served with Capt. Talcott on the survey in 1858, and the work of construction between Vera Cruz and Paso del Macho in 1862 and 1863, Mr. M. E. Lyon, who met his death at the hands of Mexican bandits while in the discharge of his duty, was most conspicuously identified with the enterprise.

Mr. Taylor is mistaken in saying that Mr. Escandon had no interests at Jalapa, however, the writer believes that his personal interests were better served by the construction of the Orizaba line.

His arrangement with Capt. Talcott, made in New York with the approval of the representative of the Mexican Government, contemplated the survey of both the Jalapa and the Orizaba routes, and his engineer corps was organized by Capt. Talcott with that end in view.

It was only after Antonio Escandon arrived in Mexico, in April, 1858, and saw the difficulty in carrying out his original instructions, that further surveys on the Jalapa route were abandoned, and a large part of the engineer corps was disbanded.

When Capt. Talcott returned to Mexico, in 1862, the construction of the line *via* Orizaba was already in progress, and he was in no way responsible for that fact.

What part the French took in promoting the construction on the Orizaba route the writer does not know, but it was said that the French engineers made such elaborate surveys for the purpose of finding a better line than Capt. Talcott's in the direction of Orizaba, that the monkeys in the Chiquihuite Mountains caught the idea and imitated them.

Mr. Taylor may be correct in his opinion that the Interoceanic has by far the better natural route, but, so far as the writer knows, even at this late day, it is an open question, between the Orizaba and Jalapa route, as to which is the best for a railroad, all things considered.

Mr. Taylor. H. M. Taylor,* M. Am. Soc. C. E. (by letter).—The writer has had no connection with the Mexican Railway, but has made frequent trips over it while in charge of the construction and reconstruction of parts of the Vera Cruz and Pacific. The Mexican Railway, a typical English product, has the good features common to all the British built lines—good alignment, good roadbed, well-maintained, good stations, good section houses—and the fault of most of them,

* Morón, Camagüey, Cuba.

namely, the sacrifice of grade to alignment. Its curves were not compensated, neither are those of the British lines in Argentina, Uruguay, or Chili. In approaching divides, like that at Ometusco, between the Valley of Mexico and the Apam Valley, on the Gulf slope, the line makes straight for the hills, holding to the valley and taking a 1.50 grade in order to get over the divide, when, by a slight sacrifice of alignment, a 1% grade could have been had, using the slope which Nature provided; or westbound, an 0.50% grade, as has been built on the Interoceanic. This error was repeated at Guadalupe, at Paso del Macho, and at the Metlac Barranca. Considering its date of construction, however, and the condition of the Science of Engineering at the time, its location is notable. Mr. Taylor.

There were several revolutions between its commencement and its completion. Mr. Escandon had interests at Cordoba, and none at Jalapa, and naturally he constructed the line where his interests lay. Cordoba, to-day, due to its water-power, has far more freight to offer than Jalapa, and, as stated by Mr. Ingram, it is fortunate that the cost of operation on such grades was not then understood, or the Mexican Railway would have been built *via* Jalapa, and the two lines would have remained one. The Mexican made directly for Mexico and tapped Puebla *via* a branch, which was the sensible thing to do (notwithstanding Mr. Wellington). The percentage of business from Mexico to Vera Cruz was so much greater than that *via* Puebla that adding the cost of the longer haul *via* Puebla to the freight to and from Mexico would have penalized the public in the City of Mexico and north and west of that point beyond any reason.

The proof that Mr. Wellington was wrong in his theory is seen in the construction, at a much later date, of the line from San Lorenzo to Oriental by the Interoceanic.

It is not the writer's object, however, to discuss these matters, but to bring before engineers who are interested just what was made of the American-built, or rather located, line. In doing this he wishes to state that it has been always his understanding that Mr. Wellington had practically nothing to do with the actual location or construction of the line. The writer was not in Mexico at the time, but has known many Americans and other foreigners who were, some of whom were in position to know. Mr. Wellington was responsible for the route; not that the route had not been looked over before, for the Palmer-Sullivan concessionaires started a line from Vera Cruz to Mexico, built it to Antigua, about 40 km., did some grading between Perote and Limon, still to be seen, and some between Irolo and San Lorenzo, likewise still to be seen.

The writer never knew definitely what stopped this work, but he has been told that it was a complaint by the Mexican Railway of the infringement of its original and perpetual concession of a line between

Mr. Taylor.

the City of Mexico and Vera Cruz. The Interoceanic was formed of a number of separate concerns such as the "Ferrocarril de Irolo", extending from Mexico to Irolo and later to Iturbe; the Puebla to San Martin Tram line, from Puebla, 40 km. north through the Valle de Nativitas; and the Tram Company from Puebla to San Juan de los Llanos, *via* San Marcos and Virreyes. The latter was bought up and connected by short pieces of line, almost always badly located and badly constructed, because of an unfortunate contract with Don Delfin Sanchez, a promoter, a wonderfully able man in many ways, but who had no knowledge of railroad operation. Also, his contract was at a fixed price per kilometer, and, naturally, it was to his interest to fit the grade to the contours as nearly as could be done.

Between Virreyes and Rubin, the Interoceanic was constructed through a wide valley, and a tangent for the whole distance was an easy proposition. One can see from Limon to Oriental with absolutely nothing in the way of a water-grade tangent. Through this the line zigzagged, up over a hill and down again, got a little nearer Tepeyahualco, a small Indian village, on basalt rocks, not worth a car of freight per week twenty years after the line was built.

From Limon to Rubin the line was fairly good, with an ascending grade of 0.73, and 2° curves. The same extended east nearly to Rio Frio; here, rough country was encountered, and a succession of grades up and down, 2.50% in both directions, with maximum curves at the top and bottom of each grade. The line ascended 38 m. to La Cima, and ran down again to Las Vigas, the natural summit of the country, the distance being 15 km. A revision of the line, built while the writer was in charge, reduced the grade to a supported 0.35 and a maximum curve of 3 degrees. The line was shortened 1¼ km., and, in this short distance, more than 1 100° of curvature were eliminated. The quantities of the revision were nearly three times those of the original line, but the cost was very nearly the same, due to the fact that nearly all the original line was in rock, and the revision was nearly all in earth.

In operation, the revision cut down the helper-engine distance 28 km.; trains in both directions were helped, and the estimate showed more than 20% per annum on the cost of making the change.

The line from Metepec to San Lorenzo was worked out on the basis of ton-kilometer cost, and when revision was made, the net returns to the Company were estimated as being more than 15 per cent. An examination of the returns of the Company after these revisions were made showed that the estimates were conservative.

Below Las Vigas the line descends on a 2.50% grade to Banderilla; then there is a light grade crossing over into another drainage, with a 2.50% adverse grade to above Bruno, descending again on a 2.50% grade to Jalapa. This work of revision was heavy, and business did

not yet justify the change there. It was close at hand in 1911, however, together with that to Las Vigas. The writer disagrees with Mr. Ingram in believing that the Company, having made two investments which proved so profitable, will not make another along the same lines when peace happily returns to Mexico. Mr. Taylor.

Below Jalapa, the revision showed that the old Camino National, along which the Mexican Tramway ran in Mr. Wellington's time, was the proper route, a 2% line with a maximum curve of 6° being found and compensated. The tonnage was calculated, and the quantity required to make the investment in the change of line profitable was determined. That, too, was not so far away when the Madero Revolution caused postponement of the question of investments in all Mexican projects excepting oil lands.

Unlike Mr. Ingram, and others of the Mexican Railway, the writer is not proud of the location of the Interoceanic. It is a fine property, and it is to be regretted that its location renders it inferior to the Mexican line as a transportation machine, when it could have been superior, as no doubt it will be when peace comes, prosperity returns, and it is made of standard gauge.

Emile Low,* M. Am. Soc. C. E. (by letter).—On March 4th, 1517, Francisco Hernandez de Cordoba discovered the coast of Yucatan, and in the following year Juan de Grijalva landed on the island now occupied by the castle of San Juan de Ulua, off Vera Cruz. On April 21st, 1519, Hernando Cortez landed on the site of the present City of Vera Cruz. On August 16th, 1519, Cortez and his bold Conquistadores left Cempoalla, the capital of the Totonac Indians, on his famous march to the Aztec capital, Tenochtitlan, the site of the present City of Mexico. His force consisted of 400 Spanish soldiers, 15 horses, with 7 pieces of artillery, augmented by several thousand Totonac Indians. Mr. Low.

The line of march passed through the Indian village of Jalapa, thence to the north of the volcano, Cofre de Perote, reaching the table-land, across this to the Indian town of Tlaxcala, where a battle was fought with the natives, in which the Spaniards were victorious. From this place the march continued to Cholula, where another battle was fought between the Conquistadores and the Cholulans, in which several thousand of the latter were slain. The ascent of the mountain then began, Cortez crossing the saddle between the volcanoes of Popocatepetl and Iztaccihuatl, descending to the town of Amecameca, and then across the valley to the capital of Montezuma which was entered November 8th, 1519, less than 3 months after leaving the shores of the Gulf of Mexico.

It is hard to believe that the route traveled was anything more than a trail, perhaps the only one between the capital and the Gulf of

* Buffalo, N. Y.

Mr. Low. Mexico, a foot-path only. There were no horses in the country, and wheeled vehicles were unknown. Horses were brought to Mexico by the Spaniards, and during the two centuries which succeeded the Conquest the journey between the coast and the interior was made on horse, or mule back, or on foot. At the beginning of the Nineteenth Century, litters (*literas*) were used between Vera Cruz and Jalapa, and a line of coaches ran thence to the capital. In 1833 the first stage line was established between Mexico and Jalapa, and was extended later to the coast.

As streams flowed in an almost direct line from the top of the table-land to the coast, making the shortest descent, this was the reason for the first line of communication chosen. If there was another one, or more, the fact was not known at the time. Later, another trail was developed to the south of Orizaba, and still later, at about the end of the Eighteenth Century, they were transformed into wagon roads, with the dignified name of *camino real,* the King's highway.

On page 1546 these two highways between Vera Cruz and the City of Mexico are mentioned. The northern, passing to the north of Cofre de Perote, built at the expense of the Consulate of Mexico and constructed with Roman splendor, to serve as a passage for all the traffic carried on by New Spain at one period, was abandoned shortly after the Independence (1823). Its towns, which were maintained by a fictitious commercial movement, were depopulated little by little, and its fields were deserted.

The National or King's Bridge—Puente del Rey, as it was called during the colonial period—56 km. out from Vera Cruz, was constructed toward the end of the Eighteenth Century by Gen. Don Manuel Rincon. In its material aspect it had the appearance of a Roman viaduct, and the structure was executed not only scientifically, but with splendor, as it changes its direction to follow the course of the road.

When Capt. Talcott landed in Vera Cruz, in January, 1858, he found the conditions as stated. From the examinations made by him, he decided that the proper line for a railroad was *via* Orizaba, and his surveys were all based on this decision.

Subsequent events absolutely justified this action, and it would have been nothing less than a national calamity for Mexico had the Jalapa route been chosen at the time.

About 1873, Don Ramon Zangroniz, of Vera Cruz, obtained a concession for a tramway from Vera Cruz to Jalapa, to be operated by animal power. He succeeded in building only a short section of it, when, in 1874, the concession was transferred to the Mexican Railway Company, Limited, which continued and completed the construction in May, 1875.

Mr. Low.

This horse tramway actually began at the Tejeria station, 15 km. out from Vera Cruz on the Mexican Railway, and then continued in a straight line to San Juan, where the main highway (which passed north from Vera Cruz) was intersected and generally followed to Jalapa, passing through the towns and villages of Zopilote, Tierra Colorada, Paso de Ovejas, Puente Nacional, Rinconada, Plan del Rio, Cerro Gordo, and Dos Rios, the distance between Vera Cruz and Jalapa being 114 km. (71 miles), with a rise of 1 361 m. (4 465 ft.), of which 1 100 m. (3 608 ft.) are made between Rinconada and Jalapa, a distance of 50 km. (31 miles), an average grade of 2.2%, although it is stated that 10% grades abound, which statement needs verification.

This tramway, extending for more than 70 miles, was the longest horse railway in the world.

The late A. M. Wellington, M. Am. Soc. C. E., landed in Vera Cruz in March, 1881, and it may not be amiss to state here that the writer and his father, Sigismund Low, were fellow-travelers on the steamer from New York, having secured service with the Mexican Central Railway, then under construction between the City of Mexico and El Paso del Norte (now Ciudad Juárez), while Wellington and his principal assistant, the late H. H. Filley, M. Am. Soc. C. E., were employees of the Mexican National Railroad, a narrow-gauge line building between the City of Mexico and Laredo on the Rio Grande. As stated by Wellington,* his first assignment was to make a reconnaissance for a railroad line from Vera Cruz to Mexico, *via* Jalapa "sufficient to determine the general possibilities of the route" and on which a corps of engineers was already engaged. The reconnaissance made by Wellington occupied only 3 days, and the resulting report was "that a 2 per cent. grade (uncompensated) was practicable". Such a conclusion was easily arrived at, as all the necessary data were available. The natural topography of the country was such that a 2% grade (uncompensated) just fitted it, although it was necessary at a number of points to use an excessive development of line in order to maintain this low grade. It may be pertinent to ask here why Wellington called this line the "American Line". He, like many other engineers not familiar with railroad building in Mexico, labored under the belief that the Mexican Railway (Vera Cruz-Mexico) was surveyed, located, and constructed by English engineers, when the very opposite was true, that honor belonging to an American engineer, Capt. Andrew Talcott, whose name and fame is indelibly connected with it.

Some time after Wellington's reconnaissance, further surveys were made, which showed a rise of 7 323 ft. in 72.64 miles. Wellington then

* "The American Line from Vera Cruz to the City of Mexico, via Jalapa, with Notes on the Best Methods of Surmounting High Elevations by Rail," *Transactions*, Am. Soc. C. E., Vol. XV, p. 791.

Mr. Low. made a comparison of his line with that of the Mexican Railway, and, regarding their respective grades, says:

"Continuous 2 per cent. (uncompensated) against a broken 4 per cent. (uncompensated); including the effect of curvature or of compensation therefor, 2.6 per cent. against 6 per cent."

It is hard to understand what method of computation was used in arriving at the comparative rates of grades, after allowing for compensation. Wellington allowed for his line, in which 20° curves occurred, a rate of 0.03 ft. per degree, which would give 0.6 ft., or an equivalent 2.6% grade. For the Mexican Railway, he assumed a rate of 0.11% which would give 2.0 ft., or an equivalent 6.0% grade, certainly a most extraordinary method of calculation. With the same rate of curve compensation, the equivalent grade would have been, on the Mexican Railway, 4.5 per cent.

After a short connection with the Mexican National Railroad, Wellington returned to the United States, but soon after entered the service of the Mexican Central Railway, and, during his connection with this railway, 1881-83, he was an ardent advocate of 2% grades, under all conditions, very high curve compensation, and momentum grades, which requirements did not always fit every line, as was shown in the case of the Guanajuato Branch-Siloa-Marfil, in which the writer, under his father, was in charge of location and construction.

The original survey for this branch line was from a point between Irapuato and Siloa, following the valley of the Guanajuato River to the city of the same name. This would have placed the junction in an undeveloped plain, and Siloa was finally selected. To reach Guanajuato from this city it was necessary either to tunnel a high foot-hill or go over the top. A 3% grade just fitted the topography, and the line was thus located. Wellington ordered a 2% grade with high curve compensation, which, starting with a shallow cut at the summit, brought the line on reaching the main valley "high up in the air", necessitating much development to get down, and almost doubling the distance. It is needless to say that this low grade line was abandoned and the 3% line built.

The present Mexican Railway was incorporated on August 20th, 1864, as the Imperial Mexican Railway Company, Limited, under the government of Emperor Maximilian, being granted a subvention (concession or subsidy) of $560 000 a year, of which $420 000 was the property of the company for 25 years dating from November 11th, 1868.

The Mexican Government also agreed not to subsidize any other railroad between Vera Cruz and the City of Mexico for 65 years from November, 1868.

The railroad *via* Jalapa, 3-ft. or narrow gauge, was subsequently built under the name of the Interoceanic Railway, a link in the present National Railways of Mexico.

Mr. Low.

It was chartered on April 30th, 1888, and purchased all the concessions granted by the Mexican Government for a railroad from Vera Cruz to Amacusac (near Puente de Ixtla) *via* Puebla and the City of Mexico. The main line *via* Puebla was opened from Mexico to Vera Cruz on April 1st, 1891, the distance being 339 miles.

Above and below Jalapa there are 3% grades. Later, about 1905, a cut-off was built between San Lorenzo and Oriental, 72 miles, which reduced the distance to 293 miles between Vera Cruz and the City of Mexico, as compared with 264 miles *via* the Mexican Railway.

The map, Plate LVIII, shows the lines of the Mexican and Interoceanic Railways between Vera Cruz and the City of Mexico.

The especial feature shown on this map is the more favorable alignment of the Mexican Railway, the sinuosities of the Jalapa line being very pronounced.

The highest elevation of the Maltrata grade on the Mexican Railway is between Boca del Monte and Esperanza, it being 2 470 m. (8 104 ft.) (although there is a slightly higher elevation, just east of San Andres, 2 485 m. (8 153 ft.) and on the Interoceanic at La Cima the elevation is 2 465 m. (8 087 ft.). There are descents on the former line aggregating about 130 m. (426.5 ft.), probably somewhat less on the latter line, so that the sums of the ascents and descents are a little in favor of the Jalapa line.

Regarding the highest elevation between Vera Cruz and the City of Mexico, Hacienda de Acocotla, between Apizaco and Huamantla, on the Mexican Railway is 2 537 m. (8 323 ft.) and, on the Interoceanic, Mena is 2 568 m. (8 425 ft.).

For a number of years, and likely now, all competitive traffic, both import and national, has been pooled by the two competing lines.

In reference to the report of Mr. Pascual Almazan on a line *via* Pueblo Viejo, Octitlan, Ixhuatlan, and San Juan Coscomatepec, it will be noted on the map, Plate LVIII, that the Mexican Railway has since built a railroad from Cordoba to the latter town. Thus, it will be seen that many of the railroad lines follow the old trails, which proves that to some extent the Indian was the pioneer engineer.

Paper No. 1372

TEMPERATURE STRESSES IN A SERIES OF SPANS

By Tresham D. Gregg, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Charles W. Martin and Tresham D. Gregg.

Synopsis.

The general problem of the temperature stresses in a series of spans arose while the writer was preparing plans for a viaduct at Little Rock, Ark., to carry a street over the tracks of the Rock Island, and the St. Louis, Iron Mountain, and Southern Railroads. The type approved by the City and the Railroad Companies was a series of six simple spans composed of girders decked with concrete, and supported on solid concrete piers.

The proposal to build the three west spans of this viaduct integral with the piers and abutment, brought up the consideration of the temperature stresses.

This paper is a general solution of this problem by the method of least work and the Castigliano theorem for one, two, and three spans of variable stiffness and inelastic abutments, and an application of the general solution to this particular case.

A convenient method for the logarithmic computation of stresses is also given, and a brief discussion of the results of the investigation, with tables of constants and of computed stresses.

The writer hopes that the problem set forth in this paper may be of interest.

FIG. 1.—WEST THIRD STREET VIADUCT, LITTLE ROCK, ARK.

FIG. 2.—WEST THIRD STREET VIADUCT, LITTLE ROCK, ARK.

In the course of his work as Bridge Designer in the Bridge Engineer's office of the Chicago, Rock Island and Pacific Railway, the writer was required to prepare detailed plans for a viaduct at Little Rock, Ark., to carry West Third Street across the tracks of the Rock Island, and the St. Louis, Iron Mountain, and Southern Railroads. The general outline of the bridge and the approximate length and character of the spans had been previously agreed upon by the two railroads concerned and the city authorities.

The type originally proposed by the City was a series of reinforced concrete arches. That finally agreed upon, however, was a series of simple spans, the outer girders of which had somewhat the appearance of arches (Figs. 1 and 2). Each of the three east spans is composed of eight steel girders covered and decked with reinforced concrete. Each of the three west spans is composed of eight reinforced concrete girders with integral reinforced concrete deck. All spans are supported by solid concrete piers, 3 ft. wide at the coping, all of which are on a more or less pronounced skew.

The problem arose from the proposal to build the three west spans integral with the piers and abutment, that is, without provision for changes in length due to temperature and shrinkage.

It is evident that such piers offer resistance to the free expansion or contraction of the spans which they support, and hence must introduce corresponding stresses. Are these stresses negligible? If they are not, and expansion must be provided for, how many joints are necessary, and where should they be placed?

It will be seen from Fig. 3 that, although the piers are similar in design, they have different angles of skew, and therefore different degrees of stiffness in the line of the viaduct. The spans under consideration are of approximately constant section, except as to the quantity of steel reinforcement. The outer or sidewalk girders are continuous over the two intermediate piers. The other six are not.

Fig. 3 shows the average span lengths and the angles of skew of the piers. The areas of steel and concrete in the several spans, and the respective average moments of inertia of the piers about axes perpendicular to the axis of the bridge are given in Table 2. The heights of the piers in Fig. 1 are given from the base to the neutral plane of the spans, in each case. Although they vary somewhat, they are assumed to be equal, for simplicity in the calculations.

First, consider the simplest case—that of a single span held between solid, inelastic abutments, by frictionless pins axially placed, as shown in Fig. 4.

Case I.—One span on fixed, inelastic support. (Fig. 4.)

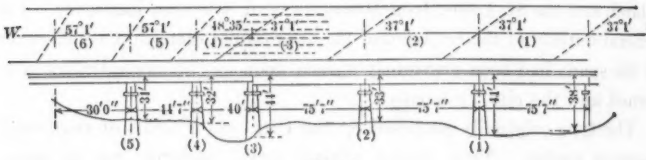

FIG. 3.

Let t equal the change of temperature, in degrees Fahrenheit;

e " " coefficient of expansion, in inches per inch per degree Fahrenheit;

E " " modulus of elasticity, in pounds per square inch;

A " " area of cross-section of span, in square inches;

l " " length of span, from center to center of piers, in inches.

Let T equal the total axial stress due to a temperature change of t degrees;

D " " change in length of span, if allowed to expand freely, $= t\ e\ l$.

Then $$T = \frac{D\ A\ E}{l}.$$

Let $$\frac{l}{A\ E} = C.$$

Substituting, we have: $$T = \frac{D}{C}.$$

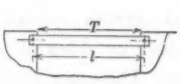

FIG. 4.

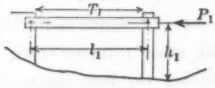

FIG. 5.

This must be added algebraically to the bending stresses in order to obtain the maximum fiber stress.

Case II.—One span fixed at both ends, one resting on an inelastic abutment, and the other on an elastic pier. (Fig. 5.)

Let the height of pier be h_1 inches; its moment of inertia, I_1; and its modulus of elasticity, E.

Suppose a force, P_1, to be applied axially with the span at the top of the pier. This force produces an axial stress, T_1, in the span, and bending stresses in the pier.

The deformation in the span due to the force, P_1, $= \frac{T_1 l_1}{A E}$, and the work done $= \frac{T_1^2 l_1}{2 A E}$.

The deflection of the pier due to the load,

$$T_1 - P_1 = (T_1 - P_1) \frac{h_1^3}{3 E I_1},$$

and the work done $= (T_1 - P_1)^2 \frac{h_1^3}{6 E I_1}$.

The total work done $= U = \frac{T_1^2 l_1}{2 A E} + \frac{(T_1 - P_1)^2 h_1^3}{6 E I_1}$.

Differentiating with respect to T_1:

$$\frac{d U}{d T_1} = \frac{T_1 l_1}{A E} + (T_1 - P_1) \frac{h_1^3}{3 E I_1} \quad \ldots\ldots\ldots\ldots\ldots (1)$$

Equating this to zero, by the principle of least work, T is found in terms of the force P_1.

If P_1 = zero, but the span changes in length, due to some other cause, such as a rise or fall in temperature, then, by Castigliano's theorem, the foregoing expression may be equated to the increment of length which the span would have if it were free from the restraint of the pier and abutment, that is,

$$\frac{T_1 l_1}{A E} + \frac{T_1 h_1^3}{3 E I_2} = D_1 \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

As before, let $\frac{l_1}{A E} = C_1$, and let $\frac{h_1^3}{3 E I_1} = B_1$.

Substitute in Equation (2) and solve.

$$T_1 = \frac{D_1}{B_1 + C_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Case III.—Single span, both supports elastic. (Fig. 6.)

The axial deformation of the span $= \frac{T_2 l_2}{A E}$, and the work of deformation $= \frac{T_2^2 l_2}{2 A E}$.

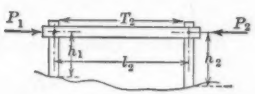

FIG. 6.

The deflection of Pier 1 $= (P_1 - T_2) \frac{h_1^3}{3 E I_1}$, and the work of deflection $= (P_1 - T_2)^2 \frac{h_1^3}{6 E I_1}$.

The deflection of Pier 2 $= (T_2 - P_2) \frac{h_2^3}{3 E I_2}$, and the work $= (T_2 - P_2)^2 \frac{h_1^3}{6 E I_1}$.

The total internal work:

$$U = (P_1 - T_2)^2 \frac{h_1^3}{6 E I_1} + \frac{T_2^2 l_2}{2 A E} + (T_2 - P_2)^2 \frac{h_2^3}{6 E I_2}.$$

Differentiating with respect to T:

$$\frac{d U}{d T_2} = (- P_1 + T_2) \frac{h_1^3}{3 E I_1} + \frac{T_1 l_2}{A E} + (T_2 - P_2) \frac{h_2^3}{3 E I_2}.$$

Let P_1 and $P_2 = 0$, and, as before, placing the resulting expression equal to the unrestrained elongation, D_2,

$$\frac{T_2 h_1^3}{3 E I_1} + \frac{T_2 l_2}{A E} + \frac{T_2 h_2^3}{3 E I_2} = D_2 \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

Solving for T_2 and making the same substitutions as before:

$$T_2 = \frac{D_2}{B_1 + B_2 + C_2} \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

Case IV.—Two spans on one inelastic abutment, and two elastic piers. (Fig. 7.)

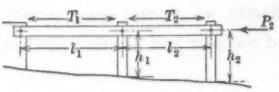

FIG. 7.

In a similar manner, the work of deformation due to the force $P_2 = U$.

$$U = \frac{T_1^2 l_1}{2 A E} + (T_1 - T_2)^2 \frac{h_1^3}{6 E I_1} + \frac{T_2^2 l_2}{2 A E} + (T_2 - P_2)^2 \frac{h_2^3}{6 E I_2}.$$

Taking the derivatives of U with respect to T_1 and T_2 successively:

$$\frac{d U}{d T_1} = \frac{T_1 l_1}{A E} + (T_1 - T_2) \frac{h_1^3}{3 E I_1} = D_1 \ldots\ldots\ldots\ldots (6)$$

$$\frac{d U}{d T_2} = (- T_1 + T_2) \frac{h_1^3}{3 E I_1} + \frac{T_2 l_2}{A E} + (T_2 - P_2) \frac{h_2^3}{3 E I_2} = D_2 . (7)$$

As before, making the B and C substitutions, we have:

$$(B_1 + C_1) T_1 - B_1 T_2 = D_1 \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

$$- B_1 T_1 + (B_1 + B_2 + C_2) T_2 = D_2 \ldots\ldots\ldots\ldots\ldots (9)$$

Solving simultaneously for T_1 and T_2:

$$T_1 = \frac{(B + B_2 + C_2) D_1 + B D_2}{(B + C)(B_1 + B_2 + C_2) - B_1^2} \quad \ldots\ldots (10)$$

$$T_2 = \frac{B_1 D_1 + (B_1 + C_1) D_2}{(B_1 + C_1)(B_1 + B_2 + C_2) - B_1^2} \quad \ldots\ldots (11)$$

If $B_1 = B_2$: $D_1 = D_2$: $C_1 = C_2$,

$$T_1 = \frac{(3B + C)}{(B + C)(2B + C) - B_2}$$

$$T_2 = \frac{(2B + C)}{(B + C)(2B + C) - B_2} \quad \ldots\ldots (11')$$

And $$T_1 = \frac{3B + C}{2B + C} T_2 \quad \ldots\ldots (10')$$

Case V.—Two spans; all supports elastic. (Fig. 8.)

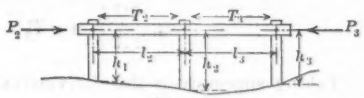

FIG. 8.

The work of deformation due to the forces, P_2 and P_3, $= U$.

$$U = (P_2 - T_2)^2 \frac{h_1^3}{6 E I_1} + \frac{T_2^2 l_2}{2 A E} + (T_2 - T_3)^2 \frac{h_2^3}{6 E I_2} + \frac{T_3^2 l_3}{2 A E} + (T_3 - P_3)^2 \frac{h_3^3}{6 E I_3}.$$

Taking successively the derivatives of U with respect to T_2 and T_3, and placing equal respectively to D_2 and D_3:

$$\frac{dU}{dT_2} = (-P_2 + T_2) \frac{h_1^3}{3 E I_1} + \frac{T_2 l_2}{A E} + (T_2 - T_3) \frac{h_2^3}{3 E I_2} = D_2 \ldots (12)$$

$$\frac{dU}{dT_3} = (-T_2 + T_3) \frac{h_2^3}{3 E I_2} + \frac{T_3 l_3}{A E} + (T_3 - P_3) \frac{h_3^3}{3 E I_3} = D_3 \ldots (13)$$

Letting P_2 and $P_3 = 0$, and making the B and C substitutions, we have:

$$(B_1 + B_2 + C_2) T_2 - B_2 T_3 = D_2 \quad \ldots\ldots (14)$$

$$-B_2 T_2 + (B_2 + B_3 + C_3) T_3 = D_3 \quad \ldots\ldots (15)$$

Solving simultaneously for T_2 and T_3, we have:

$$T_2 = \frac{(B_2 + B_3 + C_3) D_2 + B_2 D_3}{(B_1 + B_2 + C_2)(B_2 + B_3 + C_3) - B_2^2} \quad \ldots\ldots (16)$$

$$T_3 = \frac{B_2 D_2 + (B_1 + B_2 + C_2) D_3}{(B_1 + B_2 + C_2)(B_2 + B_3 + C_3) - B_2^2} \quad \ldots\ldots (17)$$

If

$$B_1 = B_2 = B_3 = B$$
$$C_2 = C_3 = C$$
$$D_2 = D_3 = D$$

$$T = \frac{D}{C + B} = T \; (= \text{Case II}).$$

Case VI.—Three spans; one inelastic abutment, and three elastic piers. (Fig. 9.)

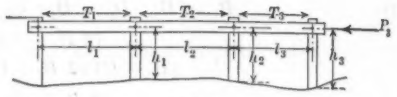

FIG. 9.

The work of deformation due to the external force, P, $= U$.

$$U = \frac{T_1^2 l_2}{2 A E} + (T_1 - T_2)^2 \frac{h_1^3}{6 E I_1} + \frac{T_2^2 l_2}{2 A E} + (T_2 - T_3)^2 \frac{h_2^3}{6 E I_2}$$
$$+ \frac{T_3^3 l_3}{2 A E} + (T_3 - P_3)^2 \frac{h_2^3}{6 E I_2}.$$

Taking successively the derivatives of U with respect to T_1, T_2, and T_3, we have:

$$\frac{d U}{d T_1} = \frac{T_1 l_1}{A E} + (T_1 - T_2) \frac{h_1^3}{3 E I_1} = D_1 \ldots\ldots\ldots (18)$$

$$\frac{d U}{d T_2} = (- T_1 + T_2) \frac{h_1^3}{3 E I_1} + \frac{T_2 l_2}{A E} + (T_2 - T_3) \frac{h_2^3}{3 E I_2} = D_2 \ldots (19)$$

$$\frac{d U}{d T_3} = (- T_2 + T_3) \frac{h_2^3}{3 E I_2} + \frac{T_3 l_3}{A E} + (T_3 - P_3) \frac{h_3^3}{3 E I_3} = D_3 \ldots (20)$$

Letting $P_3 = 0$, and making the B and C substitutions, we have:

$$(B_1 + C_1) T_1 - B_1 T_2 = D_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (21)$$
$$- B_1 T_1 + (B_1 + B_2 + C_2) T_2 - B_2 T_3 = D_2 \ldots\ldots\ldots (22)$$
$$- B_2 T_2 + (B_2 + B_3 + C_3) T_3 = D_3 \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

Solving simultaneously for T_1, T_2, and T_3, we have:

$$T_1 = \frac{D_1 + B_1 T_2}{B_1 + C_1} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

$$T_2 = \frac{B_1 (B_2 + B_3 + C_3) D_1 + (B_1 + C_1) (B_2 + B_3 + C_3) D_2}{(B_1 + C_1)(B_1 + B_2 + C_2)(B_2 + B_3 + C_3) - (B_1 + C_1) B_2^2}$$
$$\frac{+ (B_1 + C_1) B_2 D_3}{- B_1^2 (B_2 + B_3 + C_3)} \ldots (25)$$

$$T_3 = \frac{D_3 + B_2 T_2}{B_2 + B_3 + C_3} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

If $$D_1 = D_2 = D_3 = D,$$

$$B_1 = B_2 = B_3 = B,$$

and $$C_1 = C_2 = C_3 = C,$$

then $$T_1 = \frac{D + B\,T_2}{B + C} \qquad (24')$$

$$T_2 = \frac{D\,(B\,(3\,B + C) + (B + C)\,(2\,B + C))}{(B + C)\,(2\,B + C) - B\,(3\,B + C)} \qquad (25')$$

$$T_3 = \frac{D + B\,T_2}{2\,B + C} \qquad (26')$$

And $$T_1 = \frac{(2\,B + C)\,T_3}{B + C} \qquad (26'')$$

Case VII.—Three spans; all supports elastic. (Fig. 10.)

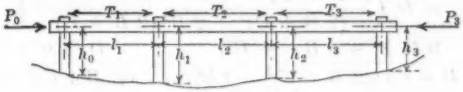

FIG. 10.

The work of deformation of the forces, P_0 and P_3, is equal to U.

$$U = (P_0 - T_1)^2 \frac{h_0^3}{6\,E\,I_0} + \frac{T_1^2\,l_1}{2\,A\,E} + (T_1 - T_2)^2 \frac{h_1^3}{6\,E\,I_1} + \frac{T_2^2\,l_2}{2\,A\,E}$$

$$+ (T_2 - T_3)^2 \frac{h_2^3}{6\,E\,I_2} + \frac{T_3^2\,l_3}{2\,A\,E} + (T_3 - P_3)^2 \frac{h_3^3}{6\,E\,I_3},$$

whence, $$\frac{d\,U}{d\,T_1} = (-P_0 + T_1) \frac{h_0^3}{3\,E\,I_0} + \frac{T_1\,l_1}{A\,E} + (T_1 - T_2) \frac{h_2^3}{3\,E\,I_2}$$

$$\frac{d\,U}{d\,T_2} = (-T_1 + T_2) \frac{h_1^3}{3\,E\,I_1} + \frac{T_2\,l_2}{A\,E} + (T_2 - T_3) \frac{h_2^3}{3\,E\,I_2}$$

$$\frac{d\,U}{d\,T_3} = (-T_2 + T_3) \frac{h_2^3}{3\,E\,I_2} + \frac{T_3\,l_3}{A\,E} + (T_3 - P_3) \frac{h_3^3}{3\,E\,I_3}$$

Making the usual substitutions, and equating to D_1, D_2, and D_3, respectively, we have:

$$(B_0 + B_1 + C_1)\,T_1 - B_1\,T_2 = D_1$$

$$-B_1\,T_1 + (B_1 + B_2 + C_2)\,T_2 - B_2\,T_3 = D_2$$

$$-B_2\,T_2 + (B_2 + B_3 + C_3)\,T_3 = D_3$$

Solving for T_1, T_2 and T_3:

$$T_1 = \frac{D_1 + B_1\,T_2}{(B_0 + B_1 + C_1)} \qquad (27)$$

$$T_3 = \frac{D_3 + B_2\,T_2}{B_2 + B_3 + C_3} \qquad (28)$$

$$T_2 = \frac{B_1 (B_2 + B_3 + C_2) D_1 + (B_0 + B_1 + C_1)(B_2 + B_3 + C_3) D_2 + (B_0 + B_1 + C_1) B_2 D_3}{(B_0 + B_1 + C_1)(B_1 + B_2 + C_2)(B_2 + B_3 + C_3) - (B_0 + B_1 + C_1) B_2^2 - B_1^2 (B_2 + B_3 + C_3)} \quad \ldots\ldots(29)$$

If $D_1 = D_2 = D_3 = D$,

$B_1 = B_2 = B_3 = B$,

and $C_1 = C_2 = C_3 = C$,

then

$$T_2' = \frac{(4B + C) D}{(2B + C)^2 - 2B^2} \quad \ldots\ldots\ldots\ldots(28')$$

$$T_1 = T_3 = \frac{D + B T_2}{2B + C} = D \frac{\left(1 + B \dfrac{4B + C}{(2B + C)^2 - 2B^2}\right)}{(2B + C)} \quad \ldots(29')$$

$$= D \left(\frac{(2B + C)^2 - 2B^2 + B(4B + C)}{(2B + C)^3 - 2B^2 (2B + C)}\right)$$

$$= \frac{D (6B^2 + 5BC + C^2)}{(2B + C)((2B + C)^2 - 2B^2))} = \frac{D (3B + C)}{((2B + C)^2 - 2B^2)}$$

$$= \frac{D (3B + C)}{(2B + C)^2 - 2B^2}: \text{ and } T_1 = T_3 = \frac{(3B + C) T_2}{4B + C} \ldots(29'')$$

Application of General Formulas.—The general formulas developed will now be applied to the determination of temperature stresses in the viaduct, the application being based on the following conditions:

First, the three concrete spans monolithic, supported without friction on Piers 3 and 4, and fixed with frictionless pins on Pier 5 and the west abutment. This is Case II.

Second, supported without friction on the abutment and Pier 3, and fixed on Piers 4 and 5. Case III.

Third, supported without friction on Pier 3, and fixed on Piers 4 and 5, and on the abutment. Case IV.

Fourth, supported without friction on the abutment and fixed on Piers 3, 4, and 5. Case V.

Fifth, fixed on all four supports. Case VI.

Proceeding now to the calculation of the various constants involved:

The constants required of each pier are: I, the moment of inertia about an axis perpendicular to the axis of the viaduct; E, the modulus of elasticity of the material; and h the height of the pier from the base to the neutral plane of the spans.

$I = I_A \sin.^2 L + I_B \cos.^2 L$, in which L is the angle made by the axis of the pier with the axis of I (perpendicular to the axis of the via-

duct). I_A is the moment of inertia of the pier about its short axis, and I_B is the moment of inertia about its long axis.

E is taken as 3 000 000 lb. per sq. in., and h is assumed in all cases to be 40 ft.

The constant, $\frac{h^3}{3\,E\,I} = B$, has the following values:

Pier 3, $B_3 = 0.11268 \times 10^{-7}$ in., Log. 2.0518419 — 10;
Pier 4, $B_2 = 0.16333 \times 10^{-7}$ in., Log. 2.2130659 — 10;
Pier 5, $B_1 = 0.24132 \times 10^{-7}$ in., Log. 2.3825920 — 10.

The constants required of each span are:

A = area, in square inches;
l = average length, in inches;
E = its modulus of elasticity;
e = its coefficient of expansion, these being combined into
$c = \frac{l}{A\,E}$ and $D = t\,e\,l$;
t = the range of temperature = 40°;
e = 0.0000055.

Span 4:

$C_3 = 0.1145 \times 10^{-7}$ in., Log. 2.0588055 — 10;
$D_3 = 0.10459$ in., Log. 9.0194902 — 10;
A = 13 960 sq. in. (including steel in terms of concrete).

Span 5:

$C_2 = 0.12798 \times 10^{-7}$ in., Log. 2.1071421 — 10;
$D_2 = 0.11790$ in., Log. 9.0715138 — 10;
A = 13 960 sq. in.

Span 6:

$C_1 = 0.13990 \times 10^{-7}$ in., Log. 2.1458177 — 10;
$D_1 = 0.132$ in., Log. 9.1205739 — 10;
A = 14 300 sq. in.

The foregoing constants are combined into the following terms, for convenience in substitution:

$C_1 + B_1 = 0.38122 \times 10^{-7}$, Log. 2.5811757 — 10;
$C_2 + B_1 + B_2 = 0.53263 \times 10^{-7}$, Log. 2.7264256 — 10;
$C_3 + B_2 + B_3 = 0.39051 \times 10^{-7}$, Log. 2.5916322 — 10;
$B_1^2 = 0.58235 \times 10^{-15}$, Log. 4.7651840 — 20;
$B_2^2 = 0.26677 \times 10^{-15}$, Log. 4.4261318 — 20.

The numerical calculations of the unit stresses in the concrete of Span 5, under the assumption of Case V, are here given to illustrate a convenient method.

Equation (16): $$T_2 = \frac{D_2 (C_3 + B_2 + B_3) + D_3 B_2}{(C_2 + B_1 + B_2)(C_3 + B_2 + B_3) - B_2^2}$$

Log. D_2 $= 9.0715138 - 10$

Log. $(C_3 + B_2 + B_3)$ $= \underline{2.5916322 - 10}$

$11.6631460 - 20 = 0.46041 \times 10^{-8}$.

Log. D_3 $= 9.0194902 - 10$

Log. B_2 $= \underline{2.2130659 - 10}$

$11.2325561 - 20 = \underline{0.17083 \times 10^{-8}}$

Numerator $= 0.63124 \times 10^{-8} = N$.

Log. $(C_2 + B_1 + B_2)$ $= 2.7264256 - 10$

Log. $(C_3 + B_2 + B_3)$ $= \underline{2.5916322 - 10}$

$5.3180578 - 20 = 0.20800 \times 10^{-14}$

Less $B_2^2 = \underline{0.02668 \times 10^{-14}}$

Denominator $= 0.18132 \times 10^{-14} = D$.

Log. N $= 11.8001945 - 20$

Log. D $= \underline{5.2584457 - 20}$

Log. T_2 $= 6.5417488$ $T_2 = 3\,481\,400$ lb.

Log. A $= \underline{4.1448854}$

Log. f_c $= 2.3968634$ $f_c = 250$ lb. per sq. in.

which is the average axial unit stress due to a change in temperature of 40°, and may be either compression or tension. The corresponding stress in the steel is $250 \times 10 = 2\,500$ lb. per sq. in.

The bending stress in Pier 5 for Case VI (that under consideration)

$$= \frac{M y}{I} = \frac{T_3 h_3 y}{I_3} = \frac{3\,481\,400 \times 480 \times 230}{509\,201\,000}$$

or $f_c = 755$ lb. per sq. in. in the extreme fiber. To this, of course, must be added algebraically the normal stress, in order to get the maximum and minimum.

The bending stresses have been found under the assumption of hinge joints at the piers. The original proposal, however, called for spans integral with the piers. As these spans, under such conditions, would be capable of transmitting considerable moment to the piers, the moment arm, h, of course, would be shortened; but the total stress,

T, at the same time, would be correspondingly increased, owing to the increased stiffness of the pier (see Equation (5)), hence the resulting stresses would not be greatly changed under an assumption of partial or even complete continuity with the supports.

Table 1 shows the arrangements of expansion joints on the viaduct according to Cases II to VI, inclusive, with the corresponding unit axial stresses in the spans, and the bending stresses in the piers.

TABLE 1.

Case.	Diagram.	Average Stress in Spans.			Bending Stress in Piers.		
		6	5	4	5	4	3
II		240	0	0	750	0	0
III		0	160	0	480	390	0
IV		480	400	0	145	1 090	0
V		0	250	300	755	115	600
VI		590	560	430	125	490	860

Ex. = Expansion joint; F = Fixed on pier; S = Sliding on pier.

Now return to the original question: that is, are the stresses due to temperature changes in this viaduct negligible?

Referring to Table 1, it is plain that, under the arrangement of Case VI, with all points of support fixed, a change of 40° Fahr. in

temperature causes severe stresses in all three spans and in Piers 3 and 4. In the spans the stresses are increased from 72 to 92% of the allowable, and the bending stresses caused in the piers are from 21 to 143% of the allowable, assuming the piers to be of 600-lb. concrete. It is interesting to note that the stresses in the spans decrease as those in the piers increase.

TABLE 2.

Span.	Area, in square inches.	Average span, in inches.	Pier.	Assumed height, in inches.	I, in inches.^{4}	Y, in inches.
6	14 300	600	5	480	509 201 000	230
5	13 960	536	4	480	752 342 100	275
4	13 960	480	3	480	1 090 534 000	327

If an expansion joint is placed at Pier 3, we have Case IV. The temperature stresses in Span 4 and Pier 3 are reduced to zero; those in Spans 5 and 6 are reduced; and the bending stresses in Piers 4 and 5, lacking the strong support of Pier 3, are increased, Pier 4 being stressed to 182% of the allowable.

If, instead of placing a joint at Pier 3 we place one at the abutment, the stresses in the spans are still further decreased, as are the bending stresses in Piers 3 and 4. Pier 5, however, takes a heavy increase in stress to 126% of the allowable unit stress in concrete.

If, in addition to a joint at the abutment, we place one at Pier 3, we have Case III, the most favorable arrangement of the five considered, the stress in Span 5 being only 27% of the allowable; but the stresses in the piers are still high, being 65 and 80% of the maximum allowable. They can be neglected, however, as the direct stress is small.

Case II produces a stress in Span 6 of 40% and in Pier 5 of 125% of the allowable unit stress.

The problem is now resolved into one of determining the relative economy of expansion joints and of reducing the maximum live-load and dead-load unit stresses by increasing the section. Case III is the only arrangement with a restrained span which would not produce prohibitive stresses in at least one of the piers. It is also to be pointed out that increasing the section of Span 5 will increase the stresses in Piers 4 and 5 in direct proportion.

The plan finally adopted was to put expansion joints at the abutment and Pier 3 and a sliding joint over Pier 5. The combination spans of the east end of the viaduct are all provided with expansion joints.

Mr. I. L. Simmons and C. E. Smith, M. Am. Soc. C. E., the Bridge Engineers, respectively, of the Chicago, Rock Island and Pacific, and the St. Louis, Iron Mountain and Southern Railroads, were responsible for the design of this bridge.

DISCUSSION

Mr. Martin. CHARLES W. MARTIN,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer has read this paper with some interest, but, save for a "look in" at the general principles, has made no attempt to follow the theoretical analysis.

In the design of reinforced concrete bridges and viaducts for the City of St. Louis, the writer, from time to time, has given considerable thought to the matter of expansion joints and stresses generated by changes of temperature. At the first glance through Mr. Gregg's paper, he was somewhat amazed at the high stress units tabulated for the structure, with the several arrangements of joints and bearings as described.

In a series of spans, temperature changes generate two distinct combinations of forces: bending combined with shear in the piers, and axial forces combined with bending in the deck. The magnitude of these forces varies directly with the moment of inertia of the pier sections in any given system of spans and piers. Thus it happens that, as in the case of the design of flat arch ribs subject to temperature changes, one frequently finds that, to reduce the stresses in the structure, he must make certain parts more flexible. In the design of a series of spans and piers, relief from high temperature stresses is obtained by a reduction of the pier sectioning.

The structure which Mr. Gregg has selected to illustrate his theory has an extremely inflexible arrangement of skewed piers, and to this is due, in accordance with his analysis, the unusually high temperature stresses. Here, the characterization "unusually high" is used advisedly, particularly as regards the axial stresses for the spans in his Cases 4 and 6 of Table 1, for if one considered any span absolutely restrained from change in length, the temperature stresses would not greatly exceed those reported.

Although the principle of Mr. Gregg's theory may be quite useful, the writer thinks he was unfortunate in the selection of a trial structure. With a structure in which the piers have such a skew, the critical guess one has to make is as to the direction of the principal distortions. Mr. Gregg has assumed that these act parallel to the longitudinal axis of the structure, whereas actually to do the "least work", these principal distortions will act in some oblique direction which will depend on the skew of the piers and the lateral restraint at the ends of the outmost spans.

Mr. Gregg. TRESHAM D. GREGG,† ASSOC. M. AM. SOC. C. E. (by letter).—The writer quite agrees with Mr. Martin that the stresses found are unusually high. In defense, however, of his selection of an example to

* St. Louis, Mo.

† Minneapolis, Minn.

illustrate the principles involved, he wishes to say that it is his experience that skewed piers are frequently necessary, and that massive piers are sometimes more economical than light, flexible bents, and always considerably safer where there is danger from collision with derailed cars or locomotives. It is freely admitted that the theory developed has small practical application, except in the type of bridge selected. Mr. Gregg.

The writer also agrees with Mr. Martin's "guess" that the distortions involving least work will be in a direction oblique to the axis of the bridge. The calculation of the true stresses in such a combination would be extremely complicated. In order to find the true state of stress in all the members—in the case where all supports are fixed—consideration must be given to the work of expansion of the several spans against piers which have a variable moment of inertia, depending on the extent to which they yield in a lateral direction; to the bending of the spans, particularly the end spans, due to the lateral movement of the piers; and to the work of torsion of the piers and bending of the spans, due to the change in angle of skew, brought about also by the lateral deflection of the piers.

The writer has reason to think that this lateral movement of the piers is a very minute quantity. If it should amount to one-half of what it would be if the spans were pivoted on the piers and the abutment ends were free to move, bending stresses in the span would be set up, which would be, if anything, greater than the axial stresses calculated under the original assumption, and bending stresses in the piers—perhaps one-fourth in amount of those tabulated in this paper—would nevertheless be combined with high torsion stresses, leaving the situation, in the writer's opinion, about as bad as before.

Paper No. 1373

THE FLOW OF WATER IN IRRIGATION CHANNELS*

By George Henry Ellis, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. H. B. Muckleston, Harold F. Gray, S. T. Harding, Allen Hazen, R. B. Sleight, W. G. Hoyt, William S. Aldrich, M. J. Orbeck and C. N. Ward and W. O'B. Henderson, and George Henry Ellis.

Synopsis.

This paper presents a study of some data recently published as *Bulletin No. 194* of the United States Department of Agriculture. An exponential formula is deduced for the flow of water, $V = C\,R^{0.69}\,S^{0.5}$, in which the coefficient, C, varies from about 40 to 140, depending on the roughness of the channel. For general conditions, the following formulas are submitted:

For concrete channels..... $V = 105\,R^{0.69}\,S^{0.5}$.
For wooden channels..... $V = 100\,R^{0.69}\,S^{0.5}$.
For earth canals..... $V = 60\,R^{0.69}\,S^{0.5}$.

Incidentally, this paper shows the need of care in the selection of a value for the coefficient of roughness. For example, Experiment No. 4, Table 1, was conducted under conditions which gave a value of n, in Kutter's formula, equal to 0.0108. Entering Fig. 3 with this value of n, it is observed that from 140 to 145 would have been a better value for C (in the writer's formula) than the 123.7 which was used. With $C = 140$ we get a velocity of 20.1.

* Presented at the meeting of March 15th, 1916.

The data on which this paper is based were taken on ditches with hydraulic radii up to about 4.0 and slopes ranging from about 0.01 to 0.0001.

Table 3 gives the 0.69th powers of radii.

Considerable interest has been manifested in this subject during recent years, and experimental work has been done by the U. S. Reclamation Service, the various State Experiment Stations, the U. S. Office of Experiment Stations, and by individuals. The Office of Experiment Stations has collected and published as a bulletin all recent available data on this subject.* This paper uses the tabulated data on pages 19 to 27 of that bulletin for the purpose of finding a simpler formula for the flow of water.

Different investigators use different methods for determining the hydraulic elements of a ditch. Those used by the Office of Experiment Stations are described in detail in the bulletin mentioned. Briefly, a stretch of canal was chosen, about 1 000 ft. long, and with conditions as nearly uniform as possible throughout its length. Bench-marks were set at each end, and several cross-sections were taken in order to determine the areas and perimeters. The discharge was measured generally with a current meter at the center of the reach chosen, and referred to readings of the water surface on the bench-marks at each end.

The claim has been made† that water can be measured to within 1% with a current meter. The writer believes that results within 2 or 3% can be obtained with this instrument under favorable conditions, but doubts whether dependence can be placed on it within less than about 5% for all sorts of conditions. Hoyt and Grover give tables‡ which seem to indicate that even this is optimistic. In setting the bench-marks for the determination of the slope, there is another chance for error. Assuming an allowable error (in feet) of $0.017\sqrt{\text{distance, in miles}}$, gives an error of 0.0074 in 1 000 ft. A slope of 0.0001—which is about as flat as any canal is built—has a fall of 0.1 ft. in that distance. The probable error in levels would then be 7.4% on a ditch having a slope of 0.0001.

* *Bulletin No. 194*, U. S. Department of Agriculture, May 10th, 1915.

† In a paper on Irrigation Hydrography, read before a conference of irrigation officials at North Yakima, Wash., December 7th and 8th, 1910.

‡ "River Discharge," pp. 111 and 112.

Water runs in a canal by merely sliding down hill—a process so simple that to make experiments and write papers on it seems almost absurd—and yet, because of the many things affecting friction, not very much is known about the flow of water, and this little paper will be worth while if it does no more than call attention to recently published data and start a discussion which may lead to the adoption of a more simple formula than that now in use.

In 1775 Chezy proposed his well-known formula for the flow of water, $V = C\sqrt{R\,S}$.

In 1869 Ganguillet and Kutter enlarged this by their empirical value of C:

$$V = \left\{ \frac{\frac{1.811}{n} + 41.6 + \frac{0.00281}{s}}{1 + \left[41.6 + \frac{0.00281}{s}\right]\frac{n}{\sqrt{R}}} \right\} \sqrt{R\,S}.$$

In 1897 Bazin attempted to shorten this by proposing a simpler value of C:

$$V = \frac{157.6}{1 + \frac{\gamma}{\sqrt{R}}} \sqrt{R\,S}.*$$

Engineers, however, had become so accustomed to thinking in terms of n, that they were loth to change. In 1911 Johnston and Goodrich proposed using an exponential formula of the form, $V = CR^pS^q$, and gave values of C and p, making q uniformly equal to 0.5 for simplicity.† This type of formula has also been advanced by Manning for open channels:

$$V = \frac{1.49}{n} R^{0.67} S^{0.5},‡$$

and by others for closed conduits.

For example,§ Lampe..... $V = 77.68\ D^{0.694}\ S^{0.555}$;

Flamant..... $V = (76.28 \text{ to } 86.38)\ D^{\frac{5}{7}}\ S^{\frac{4}{7}}$;

Williams.... $V = 67.7\ D^{0.668}\ S^{0.535}$;

Moritz..... $V = 77\ D^{0.7}\ S^{0.555}$.

† *Engineering Record*, Vol. 64, p. 542, November 4th, 1911.

‡ Parker, "The Control of Water", p. 472.

§ *Engineering Record*, Vol. 68, p. 669, December 13th, 1913.

A formula of this type is selected for the purposes of this paper, as it is easily deduced by plotting on logarithmic paper, as follows:

$$V = C\,R^p\,S^{0.5}.$$

$$\frac{V}{S^{0.5}} = C\,R^p.$$

$$\log.\ \frac{V}{S^{0.5}} = \log.\ C + p\ \log.\ R,$$

which is the equation of a straight line.

In recommending values of n for channels, the author of *Bulletin No. 194*, Frederick C. Scobey, Assoc. M. Am. Soc. C. E., has classified them according to different types. His classification has been adhered to in copying the data into Table 1, but only five of the twenty-three columns of data, which are of immediate use in this paper, are given. The first, second, fourth, fifth and sixth columns of Table 1 were copied from the bulletin, and the third, seventh, and eighth were computed by the writer. These data were plotted on Plates LIX and LX and Figs. 1 and 2, each point being marked for identification with its assigned value of n. Curves (or rather straight lines) were drawn through these points for each type of channel, and from these the values of the coefficient, C, and the angle, α, in Table 2 were taken.

TABLE 1.

Concrete, Type I.

"$n = 0.012$ for the highest grade of material and workmanship and exceptionally good conditions. The surface of the lining to be as smooth to the hand as a troweled sidewalk. The expansion joints to be so well covered that they practically fulfill the same condition. The climate and water to be such that moss does not accumulate to any great extent. The water to be practically free from shifting material. The alignment to be composed of long tangents joined by spiraled curves, while the interior of the channel must be of uniform dimensions, true to grade throughout the cross-section."

TABLE 1.—(*Continued.*)

CONCRETE, TYPE II.

"$n = 0.013$ for construction as in Type I, but with curves as in the usual mountain canyon. Same construction and alignment as in type I, but with a small amount of sand or débris in water. Construction as in type III, but in very favorable alignment or for water that carries a small amount of fine silt that will eventually form a slick coat."

No. of experiment.	Measured velocity.	Velocity by formula: $V = 114.0\ R^{0.69}\ S^{0.5}$.	Radius.	Slope.	n.	$S^{0.5}$.	$C\ RP$.
2	3.81	3.85	2.45	0.0003333	0.0130	0.0182	209.0
10	5.01	4.88	1.31	0.00126	0.0128	0.0355	141.0
13	3.65	3.64	2.54	0.0002837	0.0129	0.0168	217.0
15	2.45	2.47	1.30	0.000329	0.0132	0.0181	135.0
17	6.18	6.68	0.10	0.08244	0.0130	0.2871	21.5
20	2.06	2.06	0.58	0.0007	0.013	0.0264	78.0
21	7.10	7.19	2.13	0.0014	0.0132	0.0374	189.8

CONCRETE, TYPE III.

"$n = 0.014$ for linings made by good construction under favorable conditions. The surface to be as left by smooth-jointed forms or to be roughly troweled. Joints to be good, but causing some retardation. Alignment about equal in curves and tangents, with no spirals between. The bed to be clean and sides free from rough deposits."

The authors of the bulletin believe this is the proper value to use for most linings on moderate-sized channels.

No. of experiment.	Measured velocity.	Velocity by formula: $V = 105.8\ R^{0.66}\ S^{0.5}$.	Radius.	Slope.	n.	$S^{0.5}$.	$C\ RP$.

TABLE 1.—(*Continued.*)

WOODEN CHANNELS, TYPE I.

"$n = 0.012$ for well-constructed, clean flumes with surfaced lumber for both siding and battens. All lumber to run longitudinally. Alignment to consist of long tangents with gentle curves between. Construction to be such that the grade line will remain uniform, preventing sags and wavy alignment. A flume without battens may have a slightly lower value of n, but this difference will be inappreciable if the added length of the wetted perimeter due to the battens is considered in the design. Some very smooth grades of roofing materials used as linings also give a slightly lower value of n, but not enough to consider. If flumes are calked with oakum or other stuffing, care must be used that none projects into the water section if a high degree of efficiency is to be maintained."

No. of experiment.	Measured velocity.	Velocity by formula: $V = 123.7\ R^{0.69}\ S^{0.5}$.	Radius.	Slope.	n.	$S^{0.5}$.	$C\ R^{p}$.
57	4.49	3.85	2.28	0.0003108	0.0103	0.0176	255.0

70	2.32	2.44	1.92	0.00016	0.0125	0.0126	184.0

WOODEN CHANNELS, TYPE II.

"$n = 0.013$ for well-constructed, clean flumes of surfaced lumber and battens, following mountain contours, where the alignment will consist of about equal gentle curves and tangents. This value will also apply to flumes with alignment and grade as described in type I, but with vertical battens at intervals, with projecting calking or a slight amount of hardened asphalt or other water-proofing retarding the velocity."

No. of experiment.	Measured velocity.	Velocity by formula: $V = 114.0\ R^{0.69}\ S^{0.5}$.	Radius.	Slope.	n.	$S^{0.5}$.	$C\ R^{p}$.
63	5.81	5.61	2.12	0.000858	0.0126	0.0293	198.3
66	7.30	6.94	1.49	0.00213	0.0126	0.0462	158.0
67	7.93	7.66	1.72	0.00213	0.0127	0.0462	171.6
71	2.60	2.57	1.80	0.000225	0.0127	0.0150	173.3
72	2.08	2.09	1.96	0.000133	0.0129	0.0115	180.0
77	3.71	3.66	0.99	0.001044	0.0131	0.0323	114.8

WOODEN CHANNELS, TYPE III.

"$n = 0.014$ for flumes of very smooth interior, but with many bends or sharp curves. This value also applies to those of type I with a location such that a slight amount of hillside débris is unavoidable.

TABLE 1.—(*Continued.*)

Construction of type I, but with cracks poured with any water-proofing material that hardens in tapering drops, is also liable to come in this type. For type I except that unsurfaced lumber is used."

No. of experiment.	Measured velocity.	Velocity by formula: $V = 105.8\ R^{0.69}\ S^{0.5}$.	Radius.	Slope.	n.	$S^{0.5}$.	$C\ R^{p}$.
73	2.67	2.60	2.24	0.00020	0.0135	0.0141	189.0
74	1.64	1.66	0.40	0.000868	0.0138	0.0295	55.6
75	6.31	6.17	1.66	0.00169	0.0141	0.0411	151.0

TABLE 1.—(*Continued.*)

EARTH CANALS, TYPE III.

"n = 0.0225, although carried to one more significant figure, is given for the reason that it has long been used for this type and the tests do not disclose any reason for changing. This value for the average well-constructed canal in material which will eventually have a medium-smooth bottom, with graded gravel, grass on the edges and average alignment or silt at both sides of the bed and scattered stones in the middle, or a smooth bottom with an average amount of grass and roots forming the sides. Hardpan in good condition, clay and lava-ash soil take about this value."

No. of experiment.	Measured velocity.	Velocity by formula: $V = 60.2\ R^{0.69}\ S^{0.5}$.	Radius.	Slope.	n.	$S^{0.5}$.	$C\ RP$.

EARTH CANALS, TYPE IV.

"n = 0.025 for canals where the retarding influence of moss, growths of dense grass near the edges, or scattered cobbles begins to show. The value of n in earth channels where the maintenance is neglected commences at this value and rapidly goes up. This is a good value to use in the design of small head ditches or a small ditch to serve but one or two farms."

Earth Canals, Type V.

"$n = 0.030$ for canals subject to heavy growths of moss or other aquatic plants. Banks irregular or overhanging with dense rootlets. Bottom covered with large fragments of rock, or bed badly pitted by erosion. Values of n between 0.025 and 0.030 also cover the condition where the velocity is so high that cobbles are kept clean and unpacked in the center of the canal, but silt deposits near the sides. For values above 0.030 the channel is much choked with vegetation, very irregular, crooked, overhung with dragging trees and grasses, or there is some other condition that should not be allowed to exist in a well-kept system."

No. of experiment.	Measured velocity.	Velocity by formula: $V = 44.4\ R^{0.69}\ S^{0.5}$.	Radius.	Slope.	n.	$S^{0.5}$.	$C\ R^{p}$.

Table 2, then, gives a series of disconnected formulas for the flow of water in various types of channels, whereas one formula, or at least a uniformly varying series, is desirable, both for simplicity and to eliminate errors. With this end in view, the coefficients, C, in Table 2, were plotted on Fig. 3, and certain coefficients were assumed, as shown

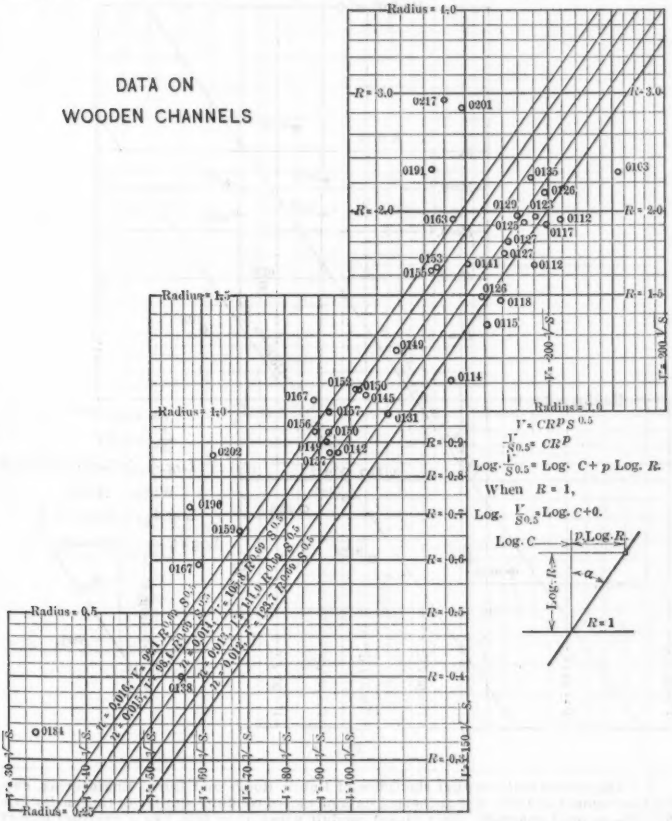

FIG. 1.

on that figure, varying on a smooth curve from 44.4 to 123.7. The exponents of R (the tangents of α in Table 2), plotted on Fig. 4, do not give so uniform a curve. The value of p might be taken as almost anything between $\frac{2}{3}$ and $\frac{3}{4}$, with little error, although the

drawing shows that its value increases with that of n. It is thought that this variation might be eliminated by using a different exponent for the slope, but the writer does not know how to find that.*

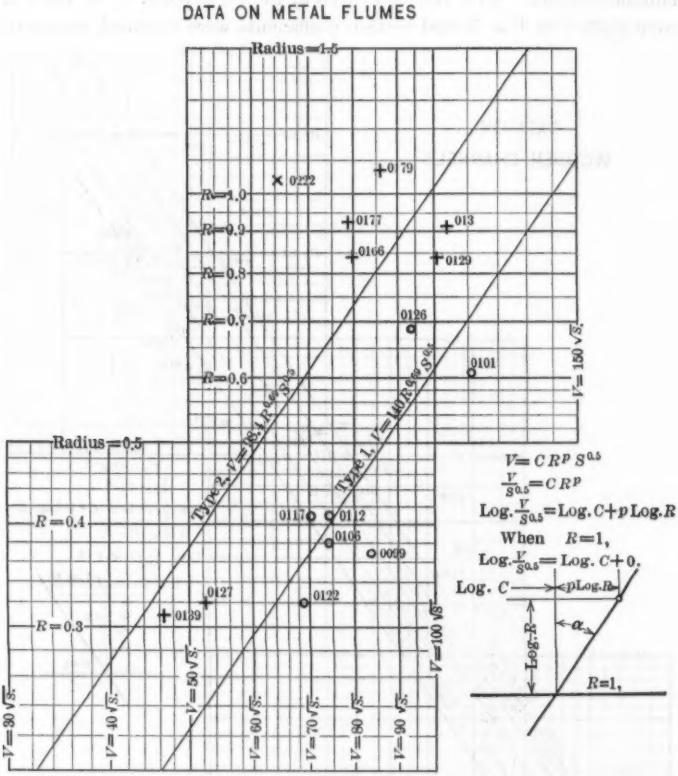

FIG. 2.

* The writer believes that the Office of Public Roads and Rural Engineering, during the summer of 1915, was gathering data on closed conduits similar to that in *Bulletin No. 194* on open channels. On a closed conduit which runs full, like a pressure pipe or siphon, the radius for a given diameter is constant, and does not vary with different velocities and slopes, the slopes being measured by the loss of head. The coefficient of roughness, of course, is a constant for any one conduit, so that the expression, $C\ R^p$, is constant. When those data are published, therefore, the ratings on each pipe can be plotted in the form, $V = (C\ R^p)\ S^q$ and the exponent of S can be determined. The average of these can then probably be applied to all the data, both in that bulletin and in this paper, and a new formula can be deduced, which, with the proper coefficient, will apply to all conditions of flow for either open or closed channels.

FIG. 3.

Messrs. Johnston and Goodrich recognized this variation, and used different exponents of R for different types of channels. This adds to the complexity of the formula, and the writer doubts whether the added accuracy is worth it. The coefficient of roughness, n, will always be a matter for judgment, and it seems inconsistent to be too precise with one part of a formula when another part is so indefinite. If this variation of p can be reduced by a different exponent of S, it should

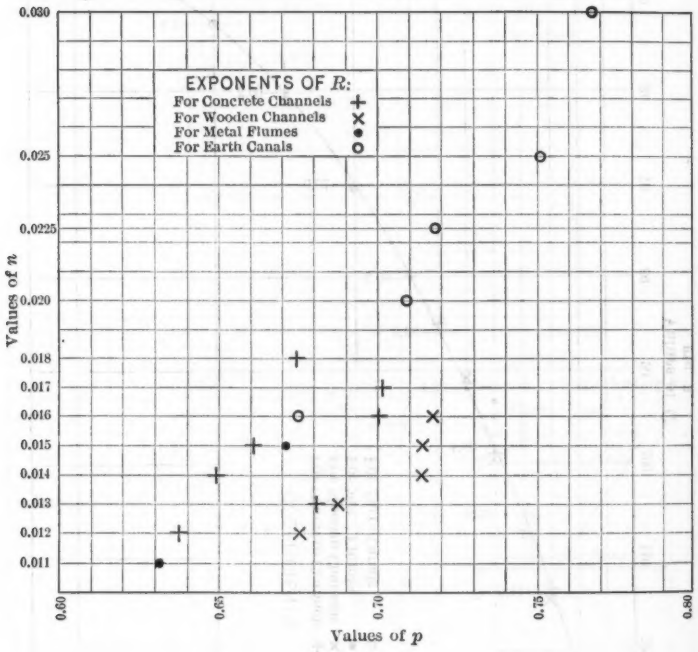

FIG. 4.

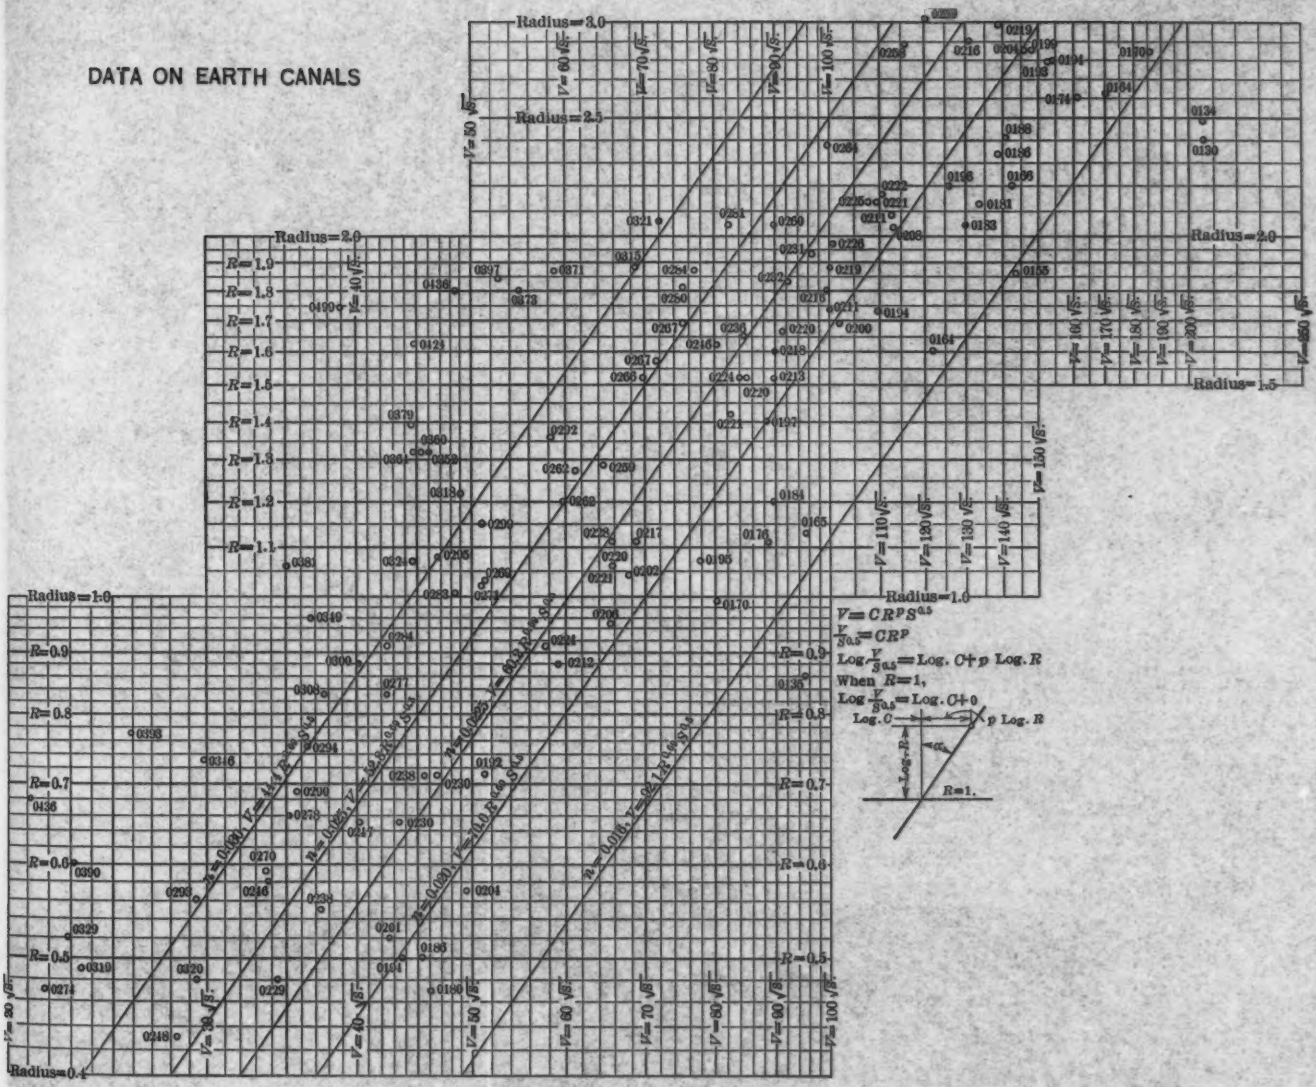
be done; but, to use a different exponent for each different type of channel makes the formula too cumbersome for ready use. The writer has merely averaged the tangents of α, in Table 2. Some of the lines by which they were obtained were more thoroughly established than others, and weights were applied accordingly, but the mean of the weighted tangents is the same as the mean of the others. The resulting formulas are represented by the diagonal lines on Plates LIX and LX

DATA ON EARTH CANALS



$V = CR^p S^{0.5}$

DISCUSSION

Mr. Muckleston.

H. B. MUCKLESTON,* M. AM. SOC. C. E. (by letter).—The principal reason for the existence of discharge formulas is for purposes of design, so that the engineer can be reasonably sure that a canal or conduit will discharge at least the quantity required by its service. If this condition is satisfied, the designer has done all he can, and may rest content.

There have been a great many such formulas devised, ranging in complexity from the very simple Chezy expression through the awful Dubuat and Kutter equations, and back to the comparatively easy experimental formulas which seem to hold the stage at present. As the author very well states, something in the way of a coefficient to allow for varying degrees of roughness has to be assumed in any event, and it seems illogical to torture a formula with odd decimal exponents or complicated coefficients, when round figures would give results quite as close to the probable truth.

The author states that the value of the exponent p might be chosen as almost anything between $\frac{2}{3}$ and $\frac{3}{4}$, with little error. The writer pleads for a value of $\frac{2}{3}$, for the sole reason that the expression can then be solved with a slide-rule, and, given a good memory and a duplex rule, the designer needs no tables, diagrams, or other aids. The writer also confesses to a decided preference for Manning's formula, because it retains the familiar symbol, n, for the roughness factor.

It has been the writer's experience that, for earthen channels at any rate, there is no constancy about any roughness factor. In one series of experimental determinations, at the same site, the value of n (Kutter) varied from 0.018 at a low stage to 0.0248 at nearly full supply. In another series, apparently made under similar conditions, but at a different site, the variations were in the opposite direction. Both series of experiments were made on a canal which had been in service 9 years.

The writer will admit that, in the case of lined channels, the designer can predict with somewhat more certainty that the assumed conditions of roughness will obtain in the finished structure, but, even then, variations in the roughness factor may be expected with varying stages.

The author makes the statement that "water runs in a canal by merely sliding down hill". It would be nearer the truth to say that it flows by falling over "itself". The early hydraulicians worked on the very convenient assumption that water flowed in a sort of series

* Calgary, Alberta, Canada.

of concentric envelopes, each of them influencing and being influenced by its neighbor on each side. It was this theory that was responsible for the intangible dimension, R, which appears directly or indirectly in every formula since Chezy's. This dimension may have a physical existence in the case of a round pipe, and possibly, as a consequence, experimental results on such pipes seem to be more consistent among themselves, but for conduits of other shapes it would appear that a further factor is needed to allow for the shapes, or to correct for the use of R, a non-existent dimension. As far as the writer is aware, the only formula which contains such a factor is attributed to Professor Claxton Fidler, and is as follows: Mr. Muckleston.

$$\text{Log. } S = x\,(m + \text{log. } V - \frac{2}{3}\,\text{log. } R) - 6.00,$$

in which m is a constant depending on shape, and x is a constant of roughness. He gives a demonstration of this formula,* with values of the coefficients, m and x, and also a modification of the formula for use with earthen channels.

Finally, it appears to the writer that, if experiments prove anything at all, it is that water in open and closed conduits does not follow the same law. In an open conduit, the slope is constant and the velocity depends on the hydraulic mean radius; in the closed conduit, the radius is constant and the velocity depends on the slope or hydraulic grade. If we take pipe experiments for pipe formulas and open-channel experiments for open-channel formulas, we shall be on surer ground, and our formulas should be more logical.

HAROLD F. GRAY,† JUN. AM. SOC. C. E.‡ (by letter).—The question of a relatively simple, yet reasonably accurate, formula for the flow of water in open channels is one which has engaged the attention of hydraulic engineers for a long time. Probably no formula has been so widely used as that of Ganguillet and Kutter, but this has always been open to considerable objection on account of its complexity, as well as certain inaccuracies. Bazin's formula is an improvement, in that it is simpler, but it is doubtful if it presents much greater accuracy than that of Kutter. It has not been used extensively by American engineers. The possibility of developing a simpler and satisfactory formula of the exponential type has been considered, particularly since the successful application of a formula of this type to the flow of water in pipes has accustomed engineers to its use. Mr. Gray.

The writer has been interested in this problem, and three years ago attempted to make comparisons between exponential formulas and those of Kutter and Bazin. From the exponential formula§ used by the writer, he developed a diagram, Fig. 5, for its use. This diagram was

* "Calculations in Hydraulic Engineering."

‡ Now Assoc. M. Am. Soc. C. E.
§ "American Civil Engineers' Pocket Book", 2d Ed., p. 858.

Mr. Gray.

used, in connection with diagrams for the Kutter and Bazin formulas, in determining what values of C were necessary, in order to obtain, for identical channels, the same velocity with the exponential formula as with the formulas of Kutter and of Bazin. Table 4 shows the variations in the coefficient necessary to bring the exponential formula into conformity with the Bazin formula. The tabular comparison for the Kutter formula has been lost.

FIG. 5.

Mr. Gray. Group II, for smooth boards, etc., Γ equals 0.290; Group III, for smooth but dirty brick or concrete, Γ equals 0.500; Group IV, ashlar masonry, Γ equals 0.833; Group V, for earth canals in very good condition, Γ equals 1.54; Group VI, for earth canals in ordinary condition, Γ equals 2.35; Group VII, for earth canals exceptionally rough, Γ equals 3.17.

Examining the variation in coefficient within each of these groups, with varying slope and hydraulic radius, it will be seen that in Group I there is a very wide variation in coefficient with different values of R; the variation with the slope is comparatively much less in amount. In Group II the variation is less than in Group I for different values of R, the variation with different slopes being about the same as in Group I. The same remark holds true with Group III. In Group IV, for ashlar masonry, the coefficient is the most nearly constant of all groups, and it would appear from this that the formula should be fairly satisfactory for canals of such type. In Groups V, VI, and VII, there is increasing variation in coefficient for different values of R, the variation with different slopes being less than the variations for different values of R, except in Group VII, where the variation for different slopes is approximately the same as for variations for different values of R.

Unfortunately, the writer was not able to pursue the study of this matter beyond the points shown in Fig. 5 and Table 4. The paper by Mr. Ellis presents some tangible data on which to work, and it is to be hoped that some means can be found to overcome the discrepancies presented by previous formulas of the exponential type. In the use of an exponential formula, however, so far as the writer can see, there does not appear to be any escape from the use of several formulas, with varying exponents for different types of channels, if accuracy within a reasonable allowable error is to be obtained. This may be avoided by the use of tables of coefficients, but in such case there is no apparent advantage over the Kutter and Bazin formulas, from a practical standpoint.

Mr. Harding. S. T. HARDING,* ASSOC. M. AM. SOC. C. E. (by letter).—The formula presented by the author is of the exponential form, and is suggested as a substitute for the well-known Kutter formula. The latter has been used so extensively, and the practice of comparing channel conditions on the basis of the value of n has become so large a part of the experience of those engaged in irrigation work, that any new formula must possess some definite advantage over Kutter's if it is to supplant it. Such an advantage may be either greater accuracy or greater convenience in use.

The author discusses some of the sources of error in experimental measurements on which any formula must be based. As the slope

* Berkeley, Cal.

Mr. Harding.

enters the result at only the 0.50th power in his formula, the error in the resulting velocity in the case cited by him would be only 3.7% on a canal with a slope as small as 0.0001. The writer made about 45 of the experiments given in *Bulletin No. 194*, on which the paper is based; and the levels were checked on these, so as to reduce the error in slope to much less than that percentage.

The accuracy of current-meter gaugings in large canals is necessarily uncertain, as the field conditions do not permit of the use of other methods which would give absolute checks. The flow and cross-section are more uniform than in many river gauging stations, and greater average accuracy should be attained. In connection with the investigations mentioned in *Bulletin No. 194*, experiments on the use of current meters in different methods of gauging were made at the same time, the particulars of which have been published.* These experiments give comparisons of the consistency of different methods of using current meters, rather than comparisons of any actual accuracy. They indicate that a consistency within 1 or 2% can be obtained. Current meters are similar to other engineering instruments; they may be used so as to give accurate results, or they may be handled so as to produce results only approximately correct, just as a transit may be handled so as to close a traverse within a minute of angle, or not within several minutes. The failure to secure accurate results is more commonly due to the conditions of use than to the fault of the instrument.

With any formula, greater accuracy cannot be expected than that with which the empirical coefficient can be selected. With Kutter's formula, it is not usual to attempt to select the value of n within about 10 per cent. A 10% difference in the value of n in that formula gives a difference in discharge for a given cross-section of from 12 to 15%; and, to carry the same discharge on the same grade, requires about 8% increase in water cross-sectional area. With the large number of experiments now available, it should usually be possible to select coefficients and exponents approximating these limits for any formula which is correct in form.

Some evidence is presented in *Bulletin No. 194* tending to show that the value of n for a given channel varies with the depth of flow or the value of the hydraulic radius. This would indicate that Kutter's formula is not correct in form and does not represent exactly the law of flow in open channels. The variations, however, are not uniform. Johnston and Goodrich have presented a diagram† showing the variation of Kutter's n with the hydraulic radius, n becoming greater as the hydraulic radius diminishes. The values of n given are those generally adopted for earth channels, and are higher than those for artificial sections such as in wood or concrete. The actual experiments

† *Engineering Record*, Vol. 64, November 4th, 1911.

Mr. Harding.

on which this diagram is based have not been published, as far as the writer is aware. It is difficult to see how dependable results on this point can be secured, except with channels of fixed and uniform cross-section and uniform surface. Such conditions are found in irrigation practice only in flumes or lined sections. In earth canals, the character of the wetted perimeter usually varies with the depth; grass and weeds may be submerged at high stages; the sides may have silt deposits; and the bottom may be clean or possibly somewhat gravelly. As the depth—and therefore value of the hydraulic radius—decreases, the value of n may easily vary, due to the greater relative importance of the character of the bottom of the canal. In *Bulletin No. 194* of the Colorado Agricultural Experiment Station, some data—also inconclusive—suggest an increase in the value of n with the discharge. In view of these conflicting and uncertain results, it seems safe to consider Kutter's formula as being sufficiently near to the theoretically correct form for all practical purposes.

Speaking broadly, Kutter's formula has no disadvantage, with reference to convenience in use, when compared with the various exponential formulas. With so many tables and curves available for the solution of Kutter's formula, actual computation in any case is unnecessary and unwarranted. The most important feature—relating to convenience in use—is the directness with which an engineer's experience in the selection of the empirical coefficient—such as n in Kutter's formula—can aid him in ascertaining the resulting velocity for any values of R and S. This can be done, at least at present for American engineers, most quickly and directly with Kutter's formula.

Some of the formulas mentioned by the author, and based on present knowledge to a sufficient extent to warrant consideration, are Kutter's, Manning's and his own. In addition, there are Bazin's new or 1897 formula,

$$V = \frac{157.6}{1 + \frac{C}{\sqrt{R}}} \sqrt{R\,S},$$

and Williams' formula for open channels, $V = C\,R^{0.67}\,S^{0.54}$.

The value of C in Bazin's formula depends on the character of the wetted perimeter. Various values are given in different books, the details for earth canals being less explicit than for similar values for Kutter's n. The same may be said regarding the values of C in Williams' formula.

Owing to the general use of Kutter's n, in defining the character of the wetted perimeter, it is desirable to have some means of correlating n with the coefficients of these different formulas. Fig. 3 gives a basis for such correlation, and the author's plotting of this figure may be accepted. The range in the value of n, included in the different

mean points plotted, is somewhat large, but further detail probably would not change the curve materially. That curve follows the equation, $C = \frac{1.25}{n - 0.002}$, quite closely, as shown in Fig. 6. The author's formula may then be written Mr. Harding.

$$V = \frac{1.25}{n - 0.002} R^{0.69} S^{0.50}.$$

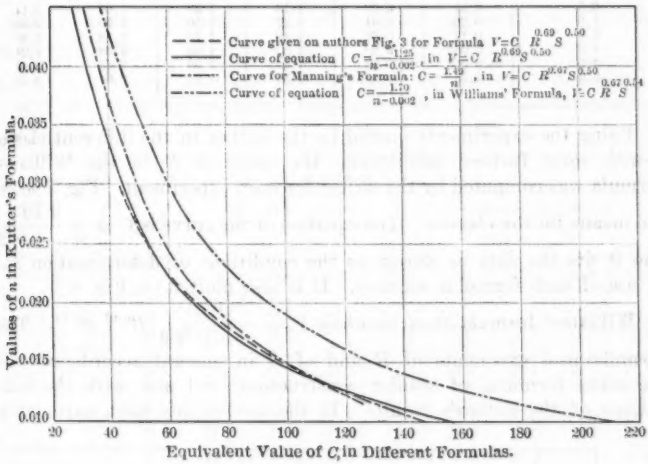

FIG. 6.

Kutter's n enters into Manning's formula directly. The author's and Bazin's new formula can be equated as follows:

$$\text{Author's formula: } \frac{V}{R^{0.69}\ S^{0.50}} = \frac{1.25}{n - 0.002}$$

$$\text{Bazin's formula: } \frac{V}{R^{0.69}\ S^{0.50}} = \frac{157.6}{1 + \frac{C}{\sqrt{R}}}\ \frac{1}{R^{0.19}}.$$

This reduces to the equation

$$C = 126.1\ (n - 0.002)\ R^{0.31} - R^{0.50}.$$

The solution of this equation for various values of n and R is given in Table 5.

The author suggests the need of using an exponent of S greater than 0.50. This is done in Williams' formula. The values of the exponent of S in the other formulas for closed conduits are so nearly the same as the 0.54 of Williams' formula that it appears safe to accept this value without elaborate investigation.

Mr. Harding.

TABLE 5.—VALUES OF C IN BAZIN'S (1897) FORMULA FOR DIFFERENT VALUES OF KUTTER'S n AND THE HYDRAULIC RADIUS.

Mean hydraulic radius, R.	VALUES OF C IN BAZIN'S (1897) FORMULA FOR THE FOLLOWING VALUES OF n IN KUTTER'S FORMULA:					
	0.012	0.015	0.020	0.0225	0.025	0.030
0.5	0.31	0.62	1.13	1.38	1.64	2.14
1.0	0.26	0.64	1.27	1.59	1.90	2.53
2.0	0.17	0.62	1.40	1.79	2.18	2.96
3.0	0.062	0.60	1.50	1.94	2.38	3.28
4.0	— 0.063	0.52	1.49	1.98	2.46	3.48
6.0	— 0.25	0.40	1.50	2.05	2.61	3.70

Using the experiments quoted by the author in the different classes —with some further subdivision—the value of C in the Williams' formula was computed by the writer for each experiment. Fig. 7 shows the means for the classes. The equation of the curve is $C = \frac{1.70}{n - 0.002}$, and it fits the data as closely as the conditions of determination and of use of such formulas warrant. It is also plotted on Fig. 6.

Williams' formula then becomes $V = \frac{1.70}{n - 0.002} R^{0.67} S^{0.54}$. This formula uses exponents of R and of S in general accordance with the other formulas of similar construction, and also with the indications of the author's results. If the use of any such exponential

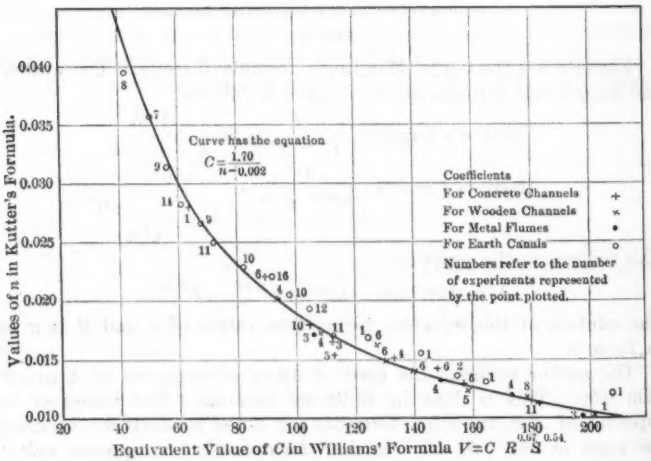

FIG. 7.

formula is considered preferable, it would appear that this one is the more logical. The computation of the 0.54th power of S requires the use of logarithms; the 0.50th power can be secured directly with the ordinary slide-rule. However, the exponent, 0.67, of R requires logarithms for the complete solution of the equation, so that this disadvantage is not of importance. Mr. Harding.

Fig. 6 and Table 5 enable one to interpret the value of Kutter's n into any of the other formulas given. Such a relation permits one to think in terms of Kutter's n, and compute by whichever formula may be preferred.

Mr. Harding.

The values of the Chezy coefficient, C, for the different formulas, are given for certain values of R, n, and S in Table 6. Parts of this table are compiled from various sources and parts are computed for this purpose. These values are all reduced to the coefficient to be applied to $\sqrt{R\,S}$. The coefficient for Bazin's formula will depend somewhat on the basis of correlation of n and C. If that given in this discussion is used, the coefficients will be the same as for the Ellis formula, as they are derived from the same relation of n and C.

For the comparisons given, the Manning formula has coefficients higher than Kutter's for the larger values of n, but, for the lower values, the agreement is quite close; this is also indicated on Fig. 6. The variation seldom exceeds 10 per cent. The difference between the coefficients of the author's and Kutter's formulas varies with the different values of R, n, and S, the agreement usually being relatively good. On the steeper slopes, the coefficients from Williams' formula exceed those from Kutter's; on the flatter slopes the reverse is true.

For all formulas, the agreement is generally within the probable error in the prediction as to the actual nature of the wetted perimeter, or the selection of the empirical coefficient. From the standpoint of results, there appears to be little choice between these formulas. Kutter's has the advantage of established usage, and Williams' perhaps has the advantage of more simple form. Exponential formulas can be developed in indefinite number, having small variations in the exponents and coefficient. It is very questionable if such differences are sufficiently great to warrant the inconvenience of their use. There may be an opportunity to bring together all available experimental data in one general study of the best exponents to be used, but such data are voluminous, and the task would be laborious. The result would probably differ from Williams' formula to such a slight extent, if at all, as hardly to repay for the effort made.

Mr. Hazen.

ALLEN HAZEN,* M. AM. SOC. C. E. (by letter).—This paper is a discussion by the author of experimental results collected by another. The author is not responsible for the experiments. The results obtained by his discussion are consistent among themselves to an extraordinary degree. The first impression is that there must be unusual merit in his procedure; further study, however, discloses a fallacy in it.

The results are consistent because of the method of classification of the data that is used as a preliminary to determining the formula which applies to each separated part. For this classification of data the Kutter formula has been used as a basis. Each section of the results thus separated is that which will produce the same value of n in the Kutter formula. The author, in reality, has found a series of exponential formulas each producing approximately the same re-

* New York City.

Mr. Hazen.

sults as the Kutter formula for a certain range. The effect of the procedure, therefore, is to demonstrate certain equivalents of the Kutter formula. It serves no other purpose. Nothing is brought out which substantiates the accuracy of the coefficients and exponents which are suggested by the author.

The method used to produce this extraordinary result is as follows: There were 269 experiments on irrigation ditches.* The data for each experiment were arranged to show, among other things, the value of n in the Kutter formula for that experiment. This is as far as Mr. Scobey carried the study. The author has taken Mr. Scobey's results and classified them according to the values of n. For the experiment in each section thus classified the value of n is nearly constant. The experiments in each section are then used to determine an exponential formula. The formula thus ascertained accounts for these particular experiments; that is to say, for those experiments in which a certain value of n is found. The exponential formula thus found corresponds approximately with the Kutter formula, with that value of n, and for the range covered. It would be impossible for it to do anything else.

The results reached by the author might have been reached more readily and with greater accuracy by a direct analysis of the Kutter formula. For instance, referring to the coefficients of the Kutter formula as tabulated by Trautwine,† for a slope of 0.001, which may be taken as representative of these experiments, the increase in the coefficients in the table from 139 for $R = 1$ to 155 for $R = 2$ is as the 0.16th power of R. As R again comes into the calculation to the extent of the 0.50th power, by Kutter's formula, for these conditions the increase in velocity is as the 0.66th power of R. In the same way, for $n = 0.020$, this exponent becomes 0.73, and for $n = 0.030$ it becomes 0.75.

Comparing these values with those found by the author and plotted in Fig. 4, the correspondence is seen to be striking. In other words, the author has found an average exponent of 0.69 simply because 0.69 gives approximately the same average increase for these experiments as would be given by the Kutter formula. There is no other basis for this conclusion. There is no analysis of the experimental results that indicates what the true exponents are, and it may be questioned whether the data in the paper are sufficient to make possible any close determination of their values.

In the same way coefficients in the several formulas found by the author may be compared with the coefficients for the Kutter formula in the Trautwine table as in Table 7.

* Described in *Bulletin No. 194*, U. S. Department of Agriculture, by Frederick C. Scobey, Assoc. M. Am. Soc. C. E.

† "Civil Engineer's Pocket-book", 19th Ed., p. 568.

Mr. Hazen.

TABLE 7.

Values of n.	Ellis. Fig. 3.	Trautwine. $S = 0.001$ $R = 1$.
0.012	123.7	122
0.013	114.0	116
0.015	98.4	99
0.017	86.0	86
0.020	70.0	71
0.030	44.4	45

The agreement of the coefficients ascertained by the author with those of the Kutter formula for the same values of n is no less striking than is the case with the exponents. It follows, for the same reason, and has no greater significance.

Those who wish to make use of the valuable data represented by this paper will do well to refer to the original publication, as the paper under discussion hardly does justice to it.

Mr. Sleight.

R. B. SLEIGHT,* JUN. AM. SOC. C. E. (by letter).—The writer has had occasion to investigate the flow of water in concrete-lined channels from the standpoint of the use of the exponential formula for velocity. The data on which this study was based are those in *Bulletin No. 194*, U. S. Department of Agriculture, by Frederick C. Scobey, Assoc. M. Am. Soc. C. E.; in *Bulletin No. 126*, U. S. Department of Agriculture, by Samuel Fortier, M. Am. Soc. C. E.; and in *Buletin No. 194*, Colorado Agricultural College Experiment Station, by Mr. V. M. Cone. An outline of the investigation and its results is offered in discussion of the paper by Mr. Ellis which has for its basic data *Bulletin No. 194* of the U. S. Department of Agriculture.

The writer has taken up only concrete-lined channels, and the expression for flow was assumed as

$$V = C_1 R^m S^n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

The exponents for R and S were not assumed arbitrarily in either case, but an attempt was made to work out both of them, and it is believed that this was successful for the exponent of S as well as for that of R. The work was done by graphical methods in all cases where possible.

For analysis, Equation (1) was divided into two parts:

$$V = B S^n, \text{ or } S = A V^{\frac{1}{n}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (a)$$

which contains the term, S, and

$$A = k R^p \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (b)$$

to take care of the term, R.

* Denver, Colo.

Mr. Sleight.

A recombination then results in

$$S = k\, R^p\, V^{\frac{1}{n}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

with the first step in its investigation a study of $\frac{1}{n}$.

All the available data were plotted logarithmically. The experiments were divided into groups so that any one set or group would have but small variation in the value of R, for example, those with R less than 1.0 in one group, those with R from 1.0 to 1.5 in another group, etc. This is illustrated by Fig. 8. In this first analysis the values of S were plotted against values of V to get a numerical value for $\frac{1}{n}$, in the equation,

$$S = A\, V^{\frac{1}{n}}.$$

As the values of R cover a small range for any one group, other than the variables taken care of in this equation, the factor of friction (or whatever we may choose to call it) is the only variable left. The center of gravity line of the plotted points, S and V, for each group of representative canals was found, and $\frac{1}{n}$ was determined for that line. The following assumptions were then made: That the value as found for the group would approximate closely the true value of $\frac{1}{n}$ for any point or measurement in that group; that the arithmetical mean of these several values of the exponent (one for each group) could be taken as the true value for the exponent of V. The writer found this to be 1.84, and the resulting expression is then:

$$S = A\, V^{1.84} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

This checks very closely that recommended by a number of authors for closed channels or pipes, giving the exponent of S in the first form of Equation (1) as 0.54.

Analysis for values for the term, A, was then taken up graphically. These values were then used with corresponding values of R, that is, R for the canal from which Equation (*a*) was determined, in a logarithmic plotting to ascertain the exponent of R. The data used necessarily had to be such as consisted of two or more measurements at different stages of the same ditch. The correct formula would show the same frictional coefficient for the ditch lining, whether the ditch were flowing full or with only a small percentage of its capacity. The writer has found available only eight such experiments. These, with their numbers, references, etc., are given in Table 8. Fig. 9 shows the logarithmic diagram. The slopes of the lines vary somewhat, show-

ing quite a range in the exponent of R. Again the arithmetical mean was taken, this average giving $R^{-1.63}$, and Equation (*b*) became

$$A = k\,R^{-1.63} \quad \ldots\ldots (4)$$

Substituting this value of A in Equation (3), there results

$$S = k\,R^{-1.63}\,V^{1.84} \quad \ldots\ldots (5)$$

which reduces to

$$V = C_1\,R^{0.88}\,S^{0.54} \quad \ldots\ldots (6)$$

The low extreme of the variation of the exponent of R is 0.76, the high extreme is 1.04. The low one is greater than shown in formulas of a similar type that have been recommended. At present,

THE VALUE OF THE EXPONENT OF R.

Mr. Sleight.

† Not all measurements on same reach; slopes taken from diagrams of Kutter's n.

however, the writer can find no justification for making an average exponent lower than 0.88. The variation from the mean is large. All the measurements seem to have been made with care. The value of 0.54 for the exponent of S, when used in ascertaining the exponent of R, gave lines of a more nearly constant slope than could be obtained when any other value was used. Therefore, in adopting the values, $R^{0.88}\,S^{0.54}$, the writer believes them to fit the conditions investigated —and conditions quite generally for concrete-lined canals—more closely than other exponential expressions; but he does not claim that the exponential expression will represent exactly the flow in open channels.

Mr. Sleight.

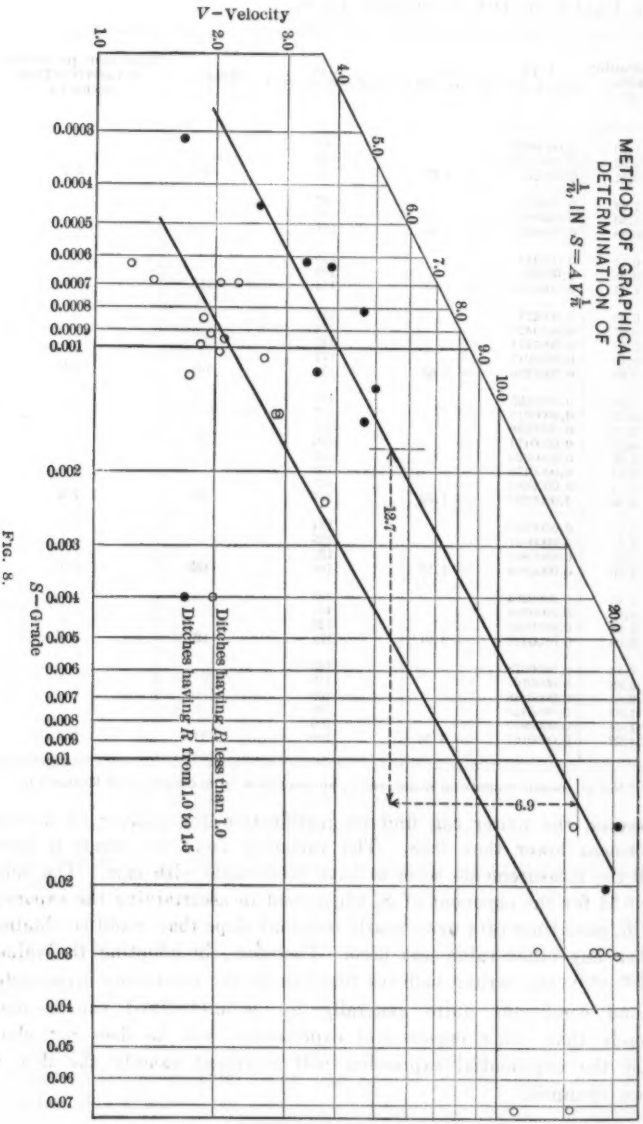

FIG. 8.

Mr. Sleight.

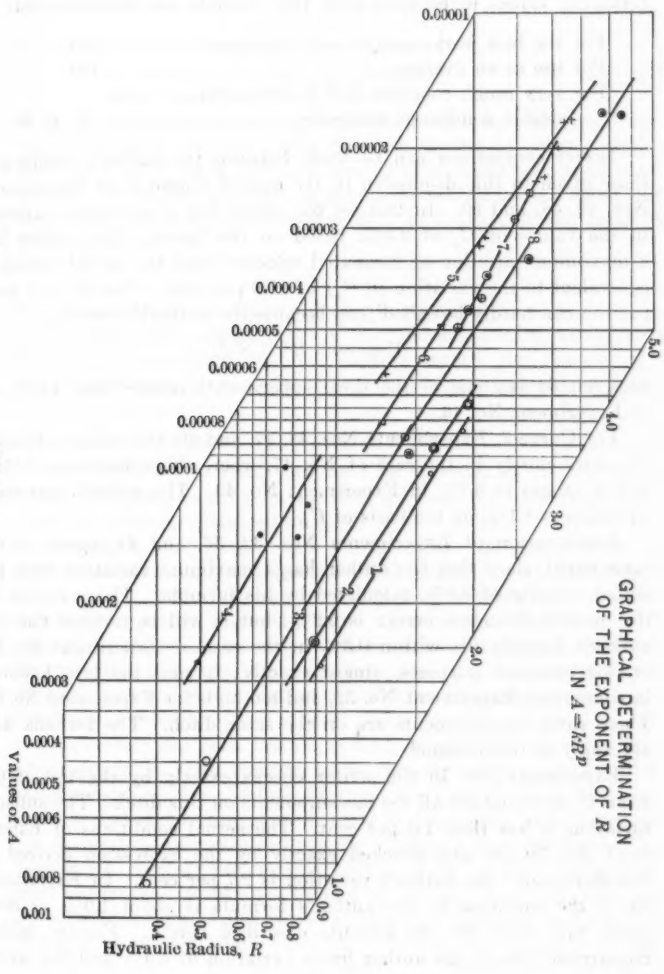

FIG. 9.

Mr. Sleight.

Equation (6) gives a comparatively constant C_1 for ditches of apparently the same character. Throughout the range of data, the following values to be used with this formula are recommended:

For the best workmanship and alignment	165
For use as an average	130
For very rough concrete, bad workmanship, or undesirable conditions generally	70 to 90

Direct comparison can be made between the author's results and those given in this discussion in the case of Curve 1, or Experiments Nos. 46, 48, and 50. In this set the writer has a maximum variation in the values of C_1 of 3.4%, based on the lowest. The author has a maximum variation of computed velocity from the actual (which is equivalent to the variation in C_1) of 17.6 per cent. Possibly this comparison can hardly be called just, because the author's formula,

$$V = 80.3\, R^{0.69}\, S^{0.5},$$

does not fit any one of the three experiments nearer than 4.64%, as in Experiment No. 46.

For Curve 2, Experiments Nos. 45, 47, and 49, the author's formula fits more closely in the case of No. 47, where the variation is 1.05%, and it ranges to 6.2% in Experiment No. 49. The writer's maximum variation is 4.1%, on the basis of C_1.

Examination of Experiments Nos. 32, 33, and 34, again on the same canal, show that the author has a maximum variation from the actual velocity of 4.5%, calculated by his formula. The variation by the method discussed herein is 5.2%; but it will be noticed that the author's formula fits within 0.3% in the case of Experiment No. 33, or, for practical purposes, almost exactly; it runs too low, however, in computing Experiment No. 32, and too high for Experiment No. 34. These three measurements are on the same ditch. The formula does not apply to this channel.

Experiment No. 15 the writer checks exactly by the use of the mean C_1 as found for all the measurements on this ditch. The author's variation is less than 1.0 per cent. The actual conditions of Experiment No. 30 are also checked exactly by the expression derived in this discussion; the author's variation is 2.7 per cent. In Experiment No. 2 the variation by the author's formula is about 1.0%, as compared with 4.5% by the formula described herein. Finally, taking Experiment No. 3, the author has a variation of 5.4% and the writer 3.4 per cent.

The last four comparisons cannot be given quite as much weight as those where more than one measurement on the same canal was

Mr. Sleight.

available. On the whole, the data for comparison are not as complete as desired; still, it seems evident that

$$V = C_1 R^{0.88} S^{0.54}$$

is nearer the correct expression than

$$V = C R^{0.69} S^{0.5}.$$

It is unfortunate that more experiments are not available on the same reach of canal, with different depths of water. Although *Bulletin No. 194* by Mr. Scobey, and such investigations as that of the author, give all the information needed on which to base canal design, they do not present the necessary data to prove that the exponential formula of the type

$$V = C_1 R^m S^n$$

will apply exactly to the flow of water in open channels.

The writer at present believes that the exponential or logarithmic expression, unmodified, will not express exactly the velocity of flow in open channels when constant exponents are attempted for all types of such channels.

Mr. Hoyt.

W. G. HOYT,* ASSOC. M. AM. SOC. C. E. (by letter).—Though this discussion deals primarily with the flow of water in natural channels, it has also some bearing on the flow of water in irrigation channels, especially those constructed of earth.

During a considerable part of the year, the channels of many streams contain a plant growth—both natural and artificial—that tends to retard the velocity of the water, increase the cross-section necessary to carry a given volume of water, and cause some local changes in slope. Apparently, such growth has sufficient effect on the regimen of the stream to change the value of n from 0.016 for earth channels in excellent condition to 0.030 for channels subject to heavy "growths of moss or other aquatic plants."

The writer has been unable to find, in any treatise on hydraulics or irrigation, any information as to the character or duration of the plant growth, or its absolute effect on the flow of the water.

Fortunately for the purpose of this discussion, but unfortunately for the purpose of collecting records of stream flow, the United States Geological Survey has maintained gauging stations at points on certain streams in Minnesota and Wisconsin where aquatic plants grow in considerable quantities during the summer, and the results obtained at these stations show the effect of the plant growth on the flow of the rivers. The gauging station on Elk River, near Big Lake, Minn., affords a typical example. Elk River, which drains an area lying chiefly in Benton and Sherbourne Counties, rises in T. 38 N.,

* Madison, Wis.

Mr. Hoyt.

R. 29 W., at approximately 1 150 ft. above sea level, flows south and east, and enters the Mississippi 20 miles up stream from Minneapolis, at an elevation of 858 ft. above sea level. At the gauging station, about 8 miles above the mouth, the drainage area is 615 sq. miles. Records collected from 1911 to 1915 show a mean flow of 200 sec-ft., a maximum of about 5 000 sec-ft., and a minimum of about 50 sec-ft. The flow during the summer varies from 100 to 300 sec-ft.

The effect of aquatic plants appears about June 1st, increases gradually through July and August, and disappears about November 1st. Between the time when the ice leaves the river and June 1st, and between November 1st and the formation of ice, a sufficient number of current-meter measurements have been made to determine the re-

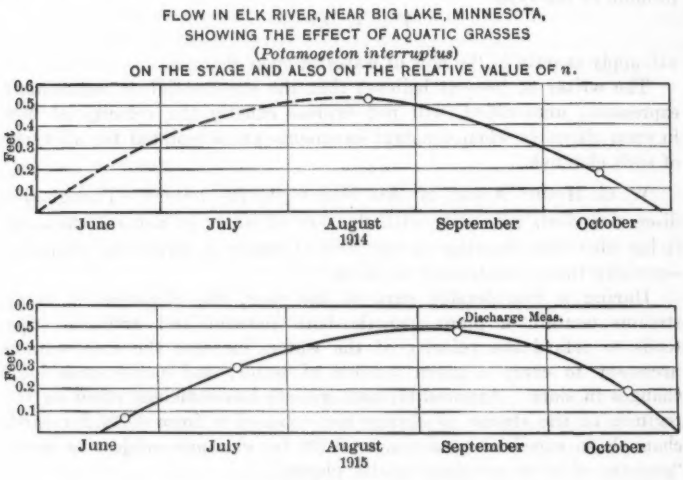

FIG. 10.

lation of flow to stage in the unobstructed channel. If the only changes in the condition of the channel are those caused by aquatic plants, it is possible to measure the effect of such growth on the stage of the river when the flow is uniform. The effect is shown graphically by Fig. 10, which has been prepared by assuming uniform conditions of flow during 1914 and 1915. The curve for 1915 is more complete than that for 1914. It is assumed that there was no back-water due to plant growth on June 1st, 1914, and November 1st. The back-water shown by the discharge measurement on August 20th was +0.53, and that of October 14th was +0.17. In 1915 the maximum effect of back-water was approximately +0.47, as shown by the discharge measurement on September 9th, and back-water from plant growth

affected the stage from June 15th to October 31st. As data relating to slope and cross-section are not available, it is not possible to show the absolute effect of this plant growth on *n*, but it is believed that the curve shows a relative effect on the value of that factor. Mr. Hoyt.

The aquatic plant most common in the streams of Minnesota and Wisconsin is *Potamogeton*, of which there are apparently sixty-five well-known species. That which grows in the Elk River is probably *Potamogeton interruptus*. The popular name is pondweed. According to MacMillan,* and Britton and Brown,† most pondweeds are submerged plants growing in ponds, lakes, and slow streams in many of the northern States and Canada. About twenty species are known in Minnesota, and some forty in Wisconsin. They are rooted in the soil under the water, rather than attached to rock or growing loose in the water. Their stems are branching, and when taken out of the water are limp, owing to poor development of woody tissues. The flowers are commonly collected on spikes, which in the spring are barely thrust above the water in order that the wind may carry the pollen from the stamens to the stigmas. Very closely related to the pondweeds are the Naiads, which may be distinguished by the solitary pistil which forms the fruit.

The growth of aquatic plants depends largely on the temperature, depth, velocity, and chemical contents of the water, the length of growing period, facility for rooting, and other factors that influence plant life. *Potamogeton* is a perennial growth, the plant dying or withering each winter, and the root remaining alive. The more luxuriant growth during 1914 was probably due to higher temperatures in that year, as the mean monthly temperature was higher than in 1915 by 4.3° in June, 8.1° in July, 6.2° in August, 1.8° in September, and 4.0° in October.

Although the aquatic growths are often spoken of as "grasses" or "mosses", few of the plants growing in streams belong to the grass family, and the "moss" said to grow in irrigation channels is undoubtedly a species of algæ.

It is not the object of this discussion to criticize Mr. Ellis' paper, but rather to submit evidence showing the effect of aquatic growth on river regimen—a subject which apparently has received little attention by engineering writers.

WILLIAM S. ALDRICH,‡ ESQ. (by letter).—This valuable paper illustrates once more the constant tendency of scientific thought in its treatment of natural phenomena. It is from the complex to the simple. After a half century of the Ganguillet-Kutter adaptation of the Chezy formula, itself then nearly a century old, we have had, in the last score of years, to reckon with Bazin's attempt to revert Mr. Aldrich.

* "Minnesota Plant Life."

† "Flora in Northern States and Canada."

‡ Fort Collins, Colo.

Mr. Aldrich.

to the simplicity of the Chezy formula. Encouraged in this logical process, the author of this paper boldly attempts the final reduction. It is, however, all the more worthy of an audience, not necessarily because it is the latest, but in that it is based on the unimpeachable data of the Government tests, conducted by the Department of Agriculture. Beyond this we may go, but scarcely at private expense, or college laboratory charge.

Examining the summary of results, Table 2, we find a tendency of the product, nC, to assume a nearly constant value; that is, this product ranges slightly above and below the value inherent in the type of canal which is usually accepted as representative of the given class of construction. This is shown in Table 9.

Plotting the values for each series, throughout the whole range, we find that the author has selected the value of C which corresponds very nearly to the general average values and the usual grade of construction, as shown in Table 10.

TABLE 9.

Type.		n.	C.	Product, nC.
Concrete	II	0.013	113.5	1.4755
	III	0.014	107.5	1.505
	IV	0.015	99.0	1.485
	VII	0.018	80.0	1.440
Wood	II	0.013	114.0	1.482
	III	0.014	106.0	1.484
	IV	0.015	99.5	1.4925
	V	0.016	91.0	1.456
Metal	I	0.011	137.0	1.507
	II	0.015	93.5	1.4025
Earth	I	0.016	90.5	1.448
	II	0.020	70.3	1.406
	III	0.0225	61.2	1.377
	IV	0.025	52.8	1.320

Referring to Fig. 3, we find, at several points along the curve, a helpful interpretation of relations between n and C. For example, the following marked points may be noted:

n.	C.	Product, nC.
0.014	105.8	1.4812
0.018	80.3	1.4454
0.0225	60.2	1.3545

These relations are more or less significant; they indicate the very close approximation of the constants selected to the actual conditions prescribed by the usual types of construction. It is thus found that the better types of wooden channels are in the same class as the

poorer types of the concrete, though even the poorer types of wooden channels hold up to the concrete remarkably well. The better types of earth channels are in the identical class of the poorer types of the wood. As might be expected, the poorer type of earth channels, within the values, 0.0225 and larger, are in a class by themselves. This grading of the relative values of the constructive types is in strict accordance with the values of the product, nC, used as a criterion, and based on Table 2. The metal channels are also clearly in a class by themselves, with this product ranging from 1.40 to 1.50, Types II and I, respectively. Mr. Aldrich.

TABLE 10.

Type.	n.	C (Ellis).	Product, nC.
Concrete channels (similar to III).....	0.014	105	1.470
Wooden channels (between III and IV).	0.0148	100	1.480
Earth channels (similar to III).....	0.0225	60	1.350

Fig. 3 is a curve of the nature of an equilateral hyperbola; that is, the product, nC = a constant (approximately). It is not intended to convey the impression that this product is, or should be, constant. The Manning formula, quoted by the author, assumes that it is a constant, and equal to 1.49. We must bear in mind that the exponent of R, in the Manning formula, is 0.67, as compared with an exponent of 0.69 in the Ellis formula.

M. J. ORBECK,* JUN. AM. SOC. C. E., and MESSRS. C. N. WARD,* and W. O'B. HENDERSON* (by letter).—In his article, "Flow of Water in Irrigation Channels",† Mr. Fred. S. Scobey has compiled a table giving the results of measurements and conditions of flow in channels of great variety, and in it the Kutter coefficient of roughness and the Chezy coefficient are included. The engineer using either of these formulas may choose a value of n or C corresponding to the channel which most nearly resembles that which he is considering. Messrs. Orbeck, Ward, and Henderson.

Owing to the fact that Manning's and Bazin's formulas are not used extensively in America, the retardation factors for these formulas were not included in Mr. Scobey's table. Either of these formulas is more convenient to use than Kutter's, which consideration led the writers to compute Manning's n and Bazin's γ for these experiments.‡ The correspondence between Kutter's n and Manning's n is quite startling, and it is probable that Manning's formula with Kutter's n, will give as accurate results as can be obtained from Kutter's formula.

* Ann Arbor, Mich.

† *Bulletin No. 194*, U. S. Department of Agriculture.

‡ These values are given in a table which is not reproduced here, but is filed in the Library of the Society.

Messrs. Orbeck, Ward, and Henderson.

Mr. Scobey's entire table has been reproduced with the exception of the columns headed "Experimenter", "Shape of Channel", "Depth Determination", "Discharge Determination", "Velocity Curve", "Temperature of Air", "Temperature of Water", and "Wind Conditions". Where such information is wanted, the reader is referred to the original publication. Columns containing Manning's n and C and Bazin's γ have been added.

All the equations considered may be written in the form:

$$V = C\sqrt{RS} \quad \ldots\ldots(1)$$

where C is given directly, as in the Chezy formula,

or by Kutter,
$$C = \frac{41.66 + \frac{0.00281}{S} + \frac{1.811}{n}}{1 + \left(41.66 + \frac{0.00281}{S}\right)\frac{n}{\sqrt{R}}} \quad \ldots\ldots(2)$$

or by Manning,
$$C = \frac{1.49}{n} R^{0.17} = C' R^{0.17} \quad \ldots\ldots(3)$$

or by Bazin,
$$C = \frac{157.6}{1 + \frac{\gamma}{\sqrt{R}}} \quad \ldots\ldots(4)$$

From Equations (3) and (4) may be derived the following:

$$n = \frac{1.49}{C} R^{0.17} \quad \ldots\ldots(5)$$

$$C' = \frac{1.49}{n} = \frac{C}{R^{0.17}} \quad \ldots\ldots(6)$$

$$\gamma = \left(\frac{157.6}{C} - 1\right)\sqrt{R} \quad \ldots\ldots(7)$$

From Equations (5), (6), and (7), Manning's n and C, and Bazin's γ, given in the table, were computed, the value of C being that given by Mr. Scobey.

These computations were made in connection with a graduate course at the University of Michigan, under the general supervision of H. W. King, M. Am. Soc. C. E., Professor of Hydraulic Engineering.

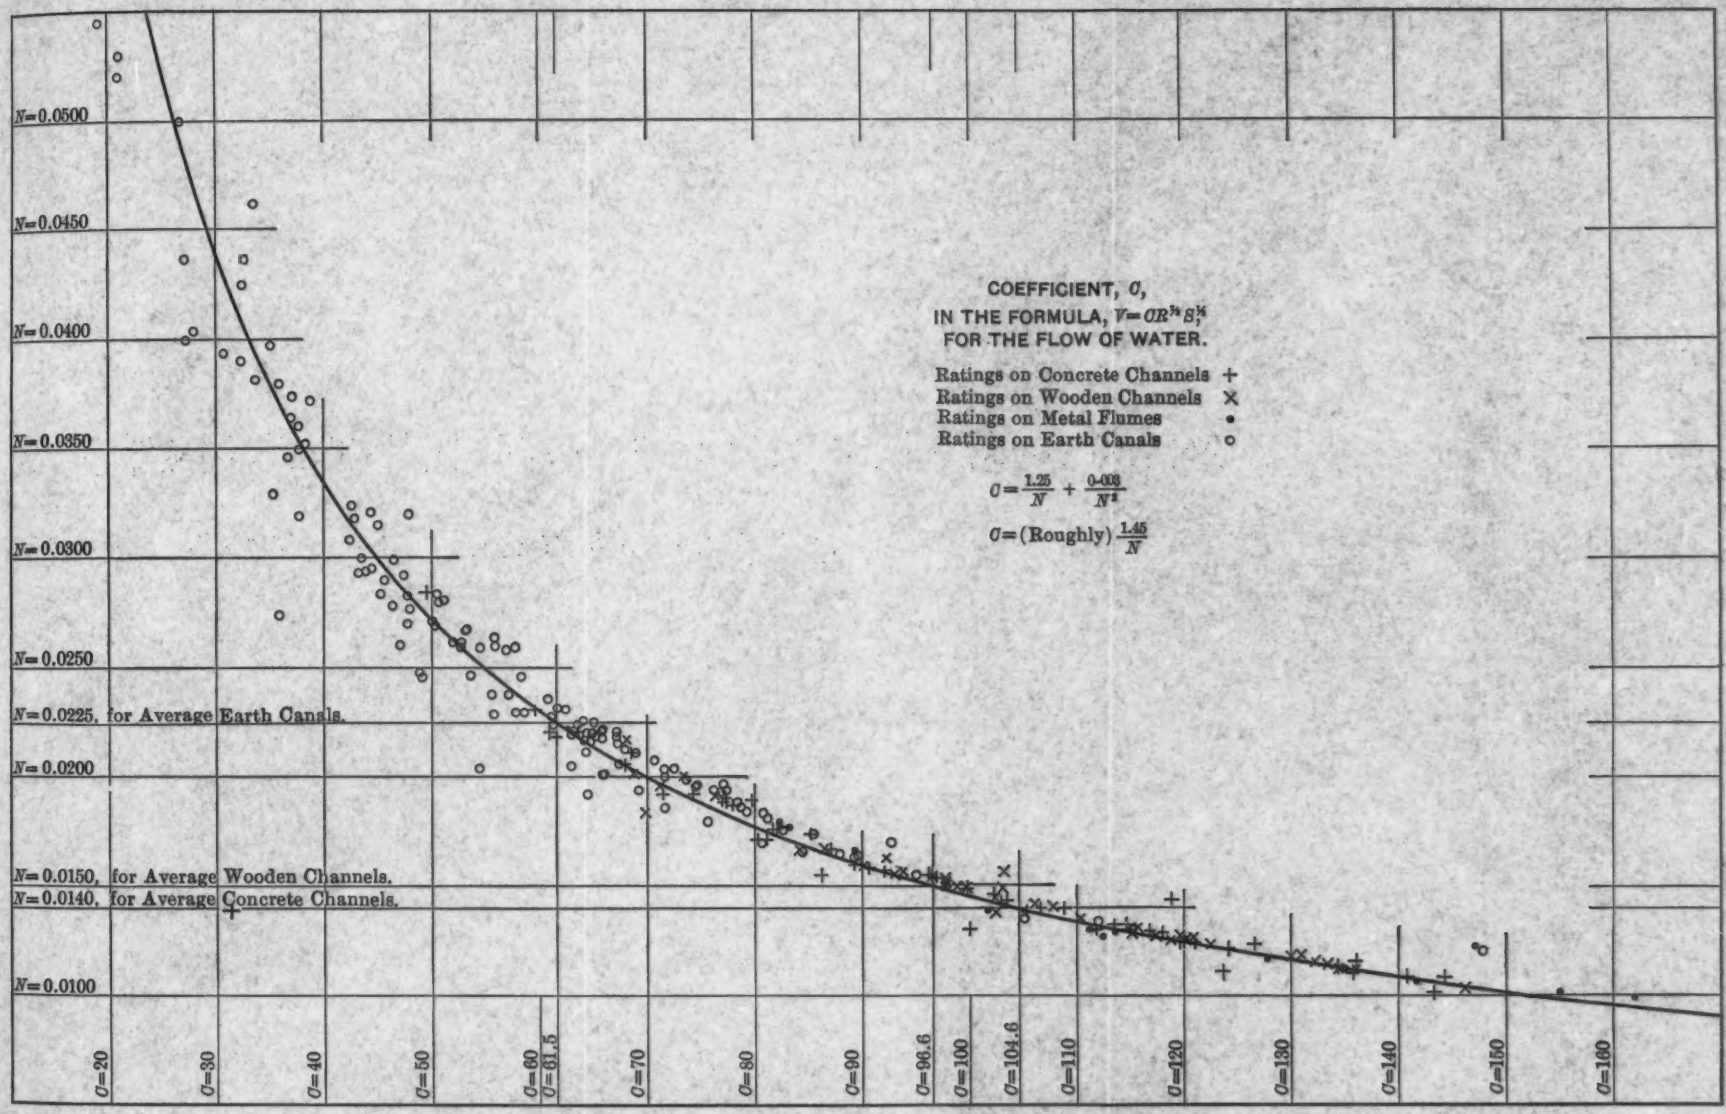
Mr. Ellis.

GEORGE HENRY ELLIS,* ASSOC. M. AM. SOC. C. E. (by letter).—In any discussion of data of this sort, some classification is almost necessary. It seemed logical to make this classification according to the roughness of the channel, and also to base any new formula on experience obtained in the use of an old one. The writer, therefore, arranged the channels in accordance with their computed values of n, which is the method to which Mr. Hazen objects.

The writer agrees with Mr. Harding and Mr. Aldrich that it is desirable to have an expression of the relation between C and n,

* Fort Shaw, Mont.

PLATE LXI.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXX, No. 1373.
ELLIS ON
FLOW OF WATER
IN IRRIGATION CHANNELS.



at least until we become accustomed to thinking in terms of C; and is indebted to both these gentlemen for the formulas submitted by them. Mr. Ellis.

Mr. Harding mentions the Williams formula, $V = CR^{0.67} S^{0.54}$, as though it were well known. The writer did not find it, either in Merriman (Ninth Edition) or in Parker's "Control of Water", both standard works on hydraulics; and had not seen it before. The object of this paper was to find a simpler formula for the flow of water, not necessarily the one deduced in the paper, but one which could be accepted by the Profession. Perhaps the Williams formula is the one. It has the different exponent for S which it was hoped would make a better curve of the points in Fig. 4. The exponent of R, 0.67, is well within the range of these points, and might fit them still better had they been obtained by $S^{0.54}$ instead of by $S^{\frac{1}{2}}$. Mr. Harding has deduced a coefficient, also, for it, $C = \frac{1.70}{n - 0.002}$, so that it can be used directly with n.

It was thought that where extreme accuracy was not required, the Williams formula might be reduced to $V = CR^{\frac{2}{3}} S^{\frac{1}{2}}$, which could be solved on almost any slide-rule, and Tables 11 and 12 have been arranged in order to compare the effects of the various exponents. The difference between $S^{0.54}$ and $S^{\frac{1}{2}}$ is surprising. Perhaps this latter expression, which is essentially the Manning formula, if used with a different coefficient, would give results sufficiently close for all practical purposes.

TABLE 11.—POWERS OF RADII.

R	$R^{0.69}$	$R^{0.67}$	$R^{\frac{2}{3}}$
0.2	0.3294	0.3402	0.3420
0.3	0.4357	0.4464	0.4481
0.4	0.5314	0.5412	0.5429
0.6	0.7030	0.7102	0.7114
0.8	0.8573	0.8611	0.8618
1.0	1.0000	1.0000	1.0000
1.5	1.3228	1.3122	1.3104
2.0	1.6133	1.5912	1.5874
3.0	2.1341	2.0878	2.0801
4.0	2.6027	2.5316	2.5198

The writer computed the values of C in Manning's formula, $V = C R^{\frac{2}{3}} S^{\frac{1}{2}}$, for each experiment, before he knew that it had already been done by Mr. Orbeck and his colleagues. The results are plotted on Plate LXI, on which the curve shows the relation between Kutter's n, as given by Mr. Scobey, and Manning's C, of $C = \frac{1.45}{n}$, roughly, and

Mr. Ellis.

this resembles the expression found by Mr. Aldrich for the writer's curve, Fig. 3. The break in the curve at about $n = 0.0225$, mentioned by Mr. Aldrich, is also quite noticeable on Plate LXI. The plotted curve is the expression, $C = \frac{1.25}{n} + \frac{0.003}{n^2}$, and is worked out in Table 13.

The writer confesses that he has been converted to the simple Manning type of formula, as its use does not require tables, diagrams, or even a special slide-rule. Computations for Plate LXI were made on an ordinary slide-rule having scales of squares and cubes. If this expression can be generally accepted and used, the term, n, will probably be gradually dropped, and in designing a concrete-lined section, for example, the velocity may be computed at $105\ R^{\frac{2}{3}}\ S^{\frac{1}{2}}$, which is nearly as simple as it can be made.

Paper No. 1374

METHOD OF DESIGNING A RECTANGULAR REINFORCED CONCRETE FLAT SLAB, EACH SIDE OF WHICH RESTS ON EITHER RIGID OR YIELDING SUPPORTS*

By A. C. Janni, M. Am. Soc. C. E.

With Discussion by Messrs. Edward Godfrey, E. P. Goodrich, Ernst F. Jonson, Charles M. Montgomery, C. A. P. Turner, Henry T. Eddy, L. J. Mensch, Charles F. Marsh, Franklin R. McMillan, and A. C. Janni.

Synopsis.

This paper deals with the incorrect method generally followed in calculating the moments of a continuous reinforced concrete flat slab resting on a system of girders.

That the elastic displacement of the supports should not be ignored, is demonstrated by theory and by a practical application.

All building codes, as far as the writer knows, overlook this important fact, and something should be done to correct the error.

There is no possibility of giving fixed formulas for designing this kind of construction; only the general lines of the method to be followed can be indicated.

Let *EFGH*, Fig. 1, be a flat slab floor, the reinforcement being parallel to *EF* and *FG*, supported by four perimetral walls, *EF*, *FG*, *GH*, *HE*; four columns, *K*, *L*, *N*, *M*; and girders as shown.

* Presented at the meeting of April 5th, 1916.

Taking into consideration the portion, *KLNM*, of that slab, suppose, for the present, that the four girders, *KL*, *LN*, *NM*, *MK*, which support it, are absolutely rigid.

Suppose now that this slab is divided into two systems of beams: System *a* parallel to the side, *KL*, and System *b* parallel to the side *LN*, as shown in Fig. 1.

If this slab carries a uniform load, *w*, per square foot, it is clear that the deflection of the beams of System *a* will not be the same for all of them, but will decrease from the center of Span *l* toward the sides, *KL* and *NM*.

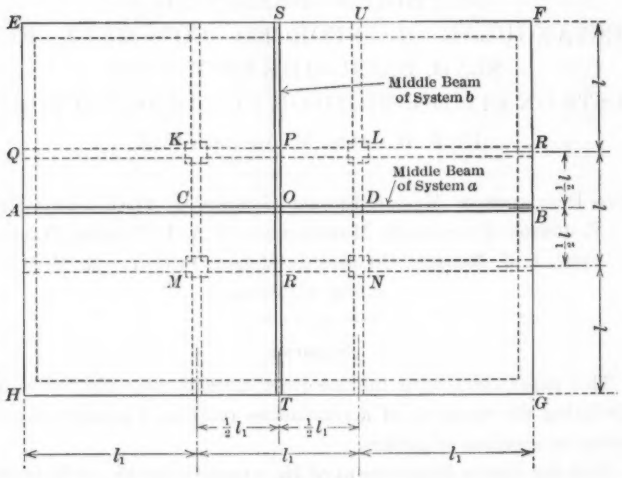

FIG. 1.

A similar condition will exist among the beams of System *b*.

Therefore, although these beams, *a* and *b*, are carrying the same uniform load, their deflections are different.

The solution of this problem, therefore, consists in finding a certain coefficient, α, by which the uniform load, *w*, should be corrected, in order to comply with the behavior of the slab.

Now, take into consideration the two beams, *CD* and *PR*. Each, being at the middle line of the slab, is the most deflected of its system; and, for the above consideration, if *w* is the uniform load assumed, αw will be the load at the center of the span, and *w* the load at the

ends. Then $(1 - \alpha)\ w$ will be the load at the center of the span of the other beam, and w that at its ends.

It will be assumed that the law of variation of the load is a parabolic one.

Let PO, Fig. 2, be the half span, PO, of PR, Fig. 1; this half beam, on account of the symmetry of the beam, PR, may be regarded as a cantilever fixed at P and under the action of a hyperstatic moment, M_o.

If F is an ideal force applied to the cantilever at O, the deformation, D, is given by:

$$D = \frac{d\,L}{d\,F} \qquad \ldots\ldots(1)$$

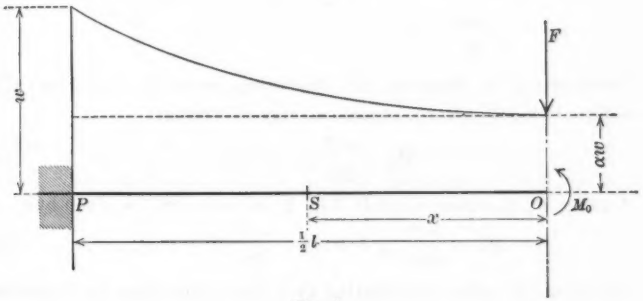

FIG. 2.

Disregarding the deformation caused by shear, and calling $\frac{1}{m}$ the coefficient of Poisson, it is known that the expression of the work, L, is given by:

$$L = \int_0^{\frac{l}{2}} \frac{m^2 - 1}{m^2} \times \frac{M^2\,dx}{2\,E\,I} \qquad \ldots\ldots(2)$$

Equation (1), therefore, may be written:

$$D = \frac{m^2 - 1}{m^2\,E\,I} \int_0^{\frac{l}{2}} M\,\frac{d\,M}{d\,F}\,dx \qquad \ldots\ldots(3)$$

For any generic section, S, Fig. 2, the value of M and $\frac{d\,M}{d\,F}$ are given by:

$$\left.\begin{aligned} M &= M_o - \alpha\,w\,\frac{x^2}{2} - \frac{w}{3}(1 - \alpha)\,\frac{x^4}{l^2} - Fx \\ \frac{d\,M}{d\,F} &= -\,x \end{aligned}\right\} \qquad \ldots\ldots(4)$$

In the foregoing expression of M there is the unknown quantity, M_O, which may be determined by the condition that the derivative of the work, L, of deformation, with respect to the hyperstatic moment, M_O, must be zero, that is to say:

$$\frac{d\,L}{d\,M_O} = 0 \qquad (5)$$

Taking the value of L from Equation (2), then Equation (5) will become:

$$\int_0^{\frac{l}{2}} M \frac{d\,M}{d\,M_O}\,dx = 0 \qquad (6)$$

where:

$$\left.\begin{aligned} M &= M_O - \alpha\, w\, \frac{x^2}{2} - \frac{w}{3}(1-\alpha)\,\frac{x^4}{l^2} \\ \frac{d\,M}{d\,M_O} &= 1 \end{aligned}\right\} \qquad (7)$$

Substituting in Equation (6) the values given by Equations (7), then Equation (6), after integration, may be written:

$$M_O = \frac{w\,l^2}{240}(1 + 9\,\alpha) \qquad (8)$$

Calling M_P the moment at P, Fig. 2, its value will be given by:

$$M_P = \frac{w\,l^2}{240}(1 + 9\,\alpha) - \frac{w\,l^2}{48}(1 + 5\,\alpha) \qquad (9)$$

Equation (3), after substituting in it the values given by Equations (4) and (8), performing the integration, and putting $F = 0$, will become:

$$E\,I\,D = \frac{m^2 - 1}{m^2} \times \frac{w\,l^4}{2\,880}(1 + 6.5\,\alpha) \qquad (10)$$

A similar expression can be obtained for the beam, $C\,D$, having the span, l_1; that is to say:

$$E\,I\,D = \frac{m^2 - 1}{m^2} \times \frac{w\,l_1^4}{2\,880}[1 + 6.5\,(1 - \alpha)] \qquad (11)$$

But the two beams, $P\,R$ and $C\,D$, must have the same deflection at O, therefore Equations (10) and (11) will furnish the other equation:

$$(1 + 6.5\,\alpha)\,l^4 = [1 + 6.5\,(1 - \alpha)]\,l_1^4$$

or

$$\alpha = \frac{7.5 - \left(\frac{l}{l_1}\right)^4}{6.5\left[1 + \left(\frac{l}{l_1}\right)^4\right]} \qquad (12)$$

Equation (12) becomes $\alpha = 1$, if $\frac{l_1}{l}$ is about $\frac{5}{3}$, that is to say, when the ratio, $\frac{L\ N}{K\ L}$, is larger than $\frac{5}{3}$, there is no advantage in the use of two-way reinforcement.

If $l = l_1$, then $\alpha = \frac{1}{2}$; that is to say, the advantage of two-way reinforcement is maximum when the slab is square.

As one cannot depend always on the effectiveness of the fixed end, P, the value of M_O, given by Equation (8), should be taken for the practical application of that equation, by assuming that the moment at P is only two-thirds of that given by Equation (9); therefore, this moment should be:

$$M_O = \frac{w\ l^2}{240}(1 + 9\ \alpha) + \frac{w\ l^2}{180}(1 + 4\ \alpha) \ldots\ldots\ldots\ldots (13)$$

or

$$M_O = \frac{w\ l^2}{720}(7 + 43\ \alpha) \ldots\ldots\ldots\ldots\ldots\ldots (14)$$

The values of M_P and M_O, given by Equations (9) and (14), are those to be substituted in the general equation of stability given by theory:

$$f\ \frac{I}{h} = \frac{m^2 - 1}{m^2}\ M \ldots\ldots\ldots\ldots\ldots\ldots (15)$$

where, f = maximum allowable stress,

I = moment of inertia,

h = distance between the neutral axis and the farther fiber,

m = coefficient of Poisson,

M = external moment.

Assuming $m = 4$, Equation (15) will become:

$$f\ \frac{I}{h} = \frac{15}{16}\ M \ldots\ldots\ldots\ldots\ldots\ldots (16)$$

Substituting in Equation (16), and giving to M the values found by Equations (9) and (14), the following equations are derived:

$$\left.\begin{aligned} f\ \frac{I}{h} &= \frac{w\ l^2}{64}(1 + 4\ \alpha) \ldots\ldots\ldots\ldots \text{at } P \\ f\ \frac{I}{h} &= \frac{w\ l^2}{768}(7 + 43\ \alpha) \ldots\ldots\ldots\ldots \text{at } O \end{aligned}\right\} \ldots\ldots (17)$$

If $l = l_1$, then, from Equation (12), $\alpha = \frac{1}{2}$, and Equations (17) will become:

$$\left.\begin{aligned} f\frac{I}{h} &= \frac{1}{21} w l^2 \text{..... at } P \\ f\frac{I}{h} &= \frac{1}{27} w l^2 \text{..... at } O \end{aligned}\right\} \text{.....(18)}$$

Having obtained, in each case, the value of α from Equation (12), by using Equations (17), the moments at the center of the span and on the supports may be found, and the calculation of the sections of the slab may be carried out by the usual methods.

Thus far, the supports of the slab, *KLNM*, have been supposed to be rigid; and, as long as this rigidity is to be expected, Equations (12) and (17) may be used legitimately; but the problem, as stated at the beginning of the paper, goes a little farther.

In fact, the four girders, *KL*, *LN*, *NM*, *MK*, supporting the panel, *KLNM*, are not rigid; they deflect with the loading of the panel, or panels, and this deflection affects, in no negligible way, the external moments as given by Equations (17), as will be shown later.

Suppose the beam, *CD*, Fig. 1, to be extended on each end to *A* and *B*, the ends, *A* and *B*, of this ideal beam, *ACDB*, being supported by the walls, *EH* and *FG*.

If D_1 is the deflection of the girder, *KM*, at the middle of its span, this deflection—considered as a deflection at *C* of the beam, *AB*—corresponds, according to theory, to a moment at Section *C* of this beam, given by:

$$M''_C = \frac{6}{5} E I_1 \frac{D_1}{l_1^2} \text{.....(19)}$$

Hence, at Section *C* of the beam, *AB*, there will be a total moment given by:

$$M_C = M'_C + M''_C \text{.....(20)}$$

The vertical reaction at *A* will be:

$$V_A = \frac{1}{2} w l_1 + \frac{M_C}{l_1} \text{.....(21)}$$

and, therefore, the maximum moment of the span, *AC*, will be:

$$M_{AC} = \frac{V_A^2}{2w} \text{.....(22)}$$

and the value of the moment at the middle of the span, CD, is found to be:

$$M_O = \left(V_A - \frac{3}{8} w l_1\right) l_1 \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

The reactions and moments for the beam, ST, are to be computed in a similar way.

The following is a practical application of the foregoing method:

Let $EFGH$, Fig. 1, be a floor system, as supposed herein, and, for a practical application of the formulas shown, let $l = 18$ ft. and $l_1 = 24$ ft.

The dead load plus live load will be assumed to be 300 lb. per sq. ft.

The moments acting on the ideal beam, PR, of the panel, $KLNM$, will be found first on the assumption that its supports at P and R are unyielding.

Equation (12) gives:

$$\alpha = 0.83.$$

Equations (17), consequently, give:

$$M_P = 6\ 561 \text{ ft-lb.}$$
$$M_O = 5\ 402.8 \text{ "}$$

In the foregoing expression for α, it should be noted, the ratio $\frac{l}{l_1}$, must be taken always so that $\frac{l}{l_1} < 1$, since the values of α cannot logically vary except between $\frac{1}{2}$ and 1. Therefore, after α is obtained and the moments for the shorter span are computed, the moments for the other beam may be determined by establishing the relations:

$$\frac{M_O}{M'_O} = \frac{l^2 (7 + 43\ \alpha)}{l_1^2 (50 - 43\ \alpha)},$$
$$\frac{M_P}{M'_C} = \frac{l^2 (1 + 4\ \alpha)}{l_1^2 (5 - 4\ \alpha)}.$$

The moments at C and O for the beam, CD, therefore, will be found to be:

$$M'_C = 4\ 588.1 \text{ ft-lb.}$$
$$M'_O = 3\ 254.7 \text{ "}$$

Taking under consideration now the beam, CD, on account of the deflection of the girder, KM, the moment at C and, consequently, the moment at O, will assume other values which must be determined.

Admitting that the deflection of the girder, KM, at its middle point, C, is 0.105 in., the moment at C, M''_C, from the beam, AB, causing this deflection, is given by:

$$M''_C = \frac{6}{5} \times 2\,000\,000 \times 722.4 \times \frac{0.105}{288^2} = 183 \text{ ft-lb.}$$

Therefore, the total moment at C will be:

$$M_C = M'_C - M''_C = 4\,588.1 - 183 = 4\,405.1 \text{ ft-lb.}$$

and the vertical reaction at A will be given by:

$$V_A = \frac{1}{2} w l_1 + \frac{M_C}{l_1} = \frac{1}{2} 300 \times 24 - \frac{4\,405.1}{24} = 3\,416.5 \text{ lb.};$$

consequently, the moment (maximum) for the span, AC, and that at O for the span, CD, will be, respectively:

$$M_{AC} = \frac{3\,432^2}{2 \times 300} = 19\,454.1 \text{ ft-lb.}$$

$$M_O = 24 \left(3\,416.5 - \frac{3}{8} \times 300 \times 24\right) = 17\,196 \text{ ft-lb.}$$

In a similar way, the moments relative to the beam, ST, could be corrected.

If the girders supporting these panels are imagined as suppressed, then the construction becomes what is commonly termed "Flat Slab Construction", the advantages of which have been rather exaggerated.

Of course, in the case of flat slab construction, beams like AB and ST would not have the greatest deflections, and other considerations should be necessary in order to carry out the design of this slab in a satisfactory way.

In the foregoing example, it will be noted, the variations of the moments of the beam, AB, due to the deflection of the girders, KL and MN, have not been taken into account.

The variations, or corrections, due to this deflection, which could be determined by the "Principle of Reciprocity" of Maxwell, together with the variations due to the deflection of the girders, KL and MN, as it has been shown in the foregoing, are enough to persuade a designer that the calculation of the moments in a reinforced concrete floor system cannot be carried out with any "ready made" set of formulas, but that each and every case is a problem by itself.

DISCUSSION

Mr. Godfrey.

EDWARD GODFREY,* M. AM. SOC. C. E. (by letter).—At the conclusion of Mr. Janni's abstruse mathematical paper he states that:

"* * * the calculation of the moments in a reinforced concrete floor system cannot be carried out with any 'ready made' set of formulas, but that each and every case is a problem by itself."

In solving a problem, Mr. Janni has found it necessary to go nearly to the mathematical limit, even using the principle of least work, which, being interpreted, means the greatest work for the practical designer to understand.

Perhaps not one practical designer in a hundred can follow the author's analysis. Those who can are generally teaching mathematics or are mathematical prodigies. Every author of a technical paper should recognize the fact that practical designers, as a class, especially designers of building work, have not the time nor the inclination—many of them have not the capacity—to follow intricate mathematical processes. For them, formulas must be pre-digested; and, after all, are not all such formulas really put into use—when they do find use—by every-day designers?

There are some instances of designing work where the higher mathematics and complex formulas are necessary, such as for suspension and cantilever bridges, and, to some extent, draw-bridges; but these are somewhat rare, and are not touched by average designers. An attempt to introduce corresponding problems into ordinary building design is apt to result in the attempt reposing just where it originated—in the journal of an engineering society.

Mr. Janni might have solved this problem without the use of the principle of least work, for the benefit of those of the "old school" who were not taught on those lines. The writer, for one, has never had occasion to use it, as he has been able to solve such problems by simpler methods. Taking the author's expression for M in Equation (4), leaving out Fx, and using the familiar form,

$$\frac{d^2 y}{d x^2} = \frac{M}{E I},$$

the first integration gives the value of M_O identical with his, when equated to 0, with $x = \frac{l}{2}$; and the second integration gives the equation of the elastic line, from which the value of $E I D$ may readily be written. This value is identical with that by the author in Equation (10). The process is very much simpler, and more easily understood.

* Pittsburgh, Pa.

Mr. Godfrey.

The writer believes that he was the first to use this method of treating a slab supported on four edges, namely, by taking the two strips across the middle of the rectangle and observing that the load on the middle square unit is divided between these two; also, that each strip carries an increasing load toward its supports, which may be assumed to vary as the ordinates of a parabola. He published this method for a square slab in 1907, and it was promptly inserted in a technical handbook,* without giving proper credit. In 1908 he applied the same method to an oblong slab freely supported on the edges. This was just in time for the Joint Committee, in its 1909 report, to use what the writer deduced, namely, when the sides of the oblong are as 2 to 3, the full load is taken in the short direction, but the Committee clung to this classical error:

$$r = \frac{l^4}{l^4 + b^4}.$$

This error will be referred to later.

Mr. Janni would have done better to ignore Poisson's ratio, which is purely theoretical, and has never had any practical demonstration in any tensile test. The writer has never found a single engineer who would apply Poisson's ratio in the case of a hollow sphere under internal pressure and reduce the thickness of the shell to less than that demanded by the ordinary strain. This is the ideal case where that ratio would apply, if it applies anywhere. This ratio is intended for a material of uniform strength and elasticity in all directions. It could not possibly apply to a combination of concrete and rods, the latter being in only two directions. The tests which appear, to some, to show the effect of Poisson's ratio show merely the effect of tensile strength in the concrete.

The writer does not see any necessity for the assumption that the supporting beams deflect and the resulting complexity introduced by it, especially in view of the very rough assumption near the top of page 1693, that the end moment is two-thirds of the fixed-ended condition. The writer does not follow all the process at the bottom of page 1694; too much is left to the imagination. It appears that the $A\ C$ portion of the beam has a uniform load. The reason for this is not evident, since this is also a middle strip in a rectangular slab.

By leaving out of consideration the deflection of the supporting girders, the solution would be greatly simplified. The moment at the middle point of a critical strip will then lie somewhere between that found by the author (ignoring Poisson's ratio) for the fixed-ended condition and that found by the writer† for the free-ended condition. A far more potent factor which affects this moment is the unloaded

* "Principles of Reinforced Concrete Construction", by Edward R. Maurer and F. E. Turneaure.

† "Concrete", 1908, p. 289.

condition of surrounding panels. In ordinary design, free-ended beams have the coefficient, $\frac{1}{8}$, in the bending moment; this is reduced to $\frac{1}{10}$ and $\frac{1}{12}$ for interior panels. Why could not similar reductions be allowed for flat slabs? This would take the problem out of the province of abstruse mathematics and place it where a building code could reach it. Mr. Godfrey.

Mr. Janni's solution is based on fixed-ended beam strips. This applies, not only to the moment, but to the value of α. To assume the beam strips only partly fixed-ended alters the value of α. Though this alteration is too small to need consideration, it is perhaps greater than the effect of deflection of the beams.

Mr. Janni finds that when the ratio of the two span lengths is as 3 to 5, the strip in the short direction will take all the load, that is, $k = 1$. The writer's solution, for freely supported edges, gives this value unity when the ratio is 2 to 3. The Joint Committee Report gives a formula which has already been referred to as a "classical error". This formula is based on assumed equal deflection of uniformly loaded strips. The strips would have to be free to deflect as simple beams. Two or three minutes of thoughtful consideration ought to convince any one familiar with the principles of mechanics that the derivation of this formula is totally wrong; and yet it permeates the entire literature of reinforced concrete. It is in the Joint Committee Report, in "Standard Practice" issued by the American Concrete Institute, in practically all the building codes, and in nearly all the books by standard authors. This error was first propagated by European regulations, so that it is international. The writer pointed it out* and has repeatedly called attention to it.

This error is only one sample of how the literature of this subject was slapped together. Authors, code writers, and committees eagerly seized on anything, with no investigation whatever as to its correctness.

This is how the plain concrete column, the rodded column, the stirrup, the bunching of steel rods in the bottom of a beam—all of them absolutely dangerous—have become, and to a large extent remain, standards, to the everlasting shame of the men responsible and to the detriment of the best form of building construction ever devised.

A peculiarity about the Joint Committee Report and "Standard Practice" is that, coupled with this erroneous formula, the rule is given that when the sides of the rectangle are as 2 to 3, the full load is to be taken the short way, in spite of the formula which shows only

* *Engineering News*, June 3d, 1909.

Mr. Godfrey.

83% of it going in that direction. A little matter of an error of 20% does not seem to bother a set of men whose only answer to criticism was to repeat exactly the same indefensible errors four years later.

It takes about ten years for an error to be eradicated after it has once been espoused by the men who consider themselves authorities, no matter how clearly it is demonstrated. The writer hammered about that long on under pressure on dams before it began to be acknowledged to be the standard thing to do, namely, to design a dam to resist upward pressure. He has been hammering nearly that long on the rodded column and the stirrup, and the point has been reached where no engineer who reads English will dare to take up a public defense of either the stirrup or the rodded column.

The flat slab, supported on all edges on girders, does not find very many users. The flat slab supported on posts does find many users, and these users have set up a series of unscientific tests, which have been interpreted to suit themselves, and on which to base their standards of design. Then they have to call in Poisson's ratio, and invent such terms as bond-shear, and set up hypotheses as to new and strange properties of the combination of steel and concrete, all to hide the fact that tension in the concrete is performing the work that they would fain have engineers believe is being performed by the steel because of the "patented" way in which it is placed.

It is beginning now to be realized that there is a static limit below which the bending moment in a flat slab cannot possibly lie. The writer pointed this out,* in 1912, and has reiterated it at different times since then. Proponents of the flat slab, who can pass their hand over a bending moment and then show the audience that it is only half as great as before, and then repeat the trick on the same bending moment, no longer awe an audience of engineers. As the writer pointed out† in 1915, the concrete in a whole slab may be taking six times as much tension as the steel. These advocates of flat slabs attribute all this work to the steel because, forsooth, "tension in concrete is not to be relied upon permanently"—the very reason that all tension in the concrete should be accounted for and additional steel supplied to take it, for the sake of safety.

Tests ought to be made by the Federal Government, not by patent owners, interpreted by their hired experts. These tests ought to be on actual structures with columns only capable of sustaining one floor—not great first-story columns in a high building, or large piers sustaining a small slab, for the columns play a large part in flat slab tests; not spot loads in the middle of a wide expanse of floor; and not exterior panels supported by deep girders on walls. All these misleading features characterize the tests of record. No long row

* *Engineering News*, February 29th, 1912.

† In a paper before the American Concrete Institute in February, 1915.

of panels completely across a building has been tested. No exterior line of panels without a deep girder or a wall has been tested. Mr. Godfrey.

The writer made the recommendation to the Director of the Bureau of Standards, in the presence of a number of concrete engineers, that the Bureau put up sample structures and test them to destruction. No high-cost testing machine, no matter how perfect, can ever discover what a rodded column will do in a building, for, the more perfect the machine and the more ideal the test, the less the value of the results.

Tests where stress in the steel is measured have very little value, for the following reasons:

(*a*) The concrete is at the same time taking many times as much tension as the steel.

(*b*) The concrete may crack, and then all of this tension is in the steel.

(*c*) Measurements with a strain gauge, through the medium of two holes dug into the concrete to the steel, do not, in fact, tell the actual unit stress in the steel, but only the average unit stress in the measured length. If a crack occurs in this length, the unit stress may be very greatly increased for a very short length, but the effect in elongation of this is distributed over the full gauged length. This phase of the result of strain gauge measurements on embedded steel has received no attention.

Flat slab rules of design are being codified, and it behooves independent engineers to take up the question before patent owners mess it up, as they have done in the case of general design in reinforced concrete. Present standards, with their plain concrete columns, their rodded columns, their stirrups or short shear members, their rods bunched in the bottom of beams—every one wreck breeders—are an outrage and a disgrace. Engineers who are interested in sustaining the honor of the Profession should do all in their power to stem the tide of wrecks that has flowed in the last ten years, due to bad design—almost wholly standard design—by demanding safe design.

To this end the theory of flat slabs ought to be simplified, rather than the reverse. The simplest criterion is to consider a slab on rows of columns just as a slab would be considered on rows of beams. Commercial rules and the Chicago ruling will not meet this criterion, and no engineer has appeared to show why they should not.

E. P. Goodrich,* M. Am. Soc. C. E. (by letter).—For the last five or six years the writer has used a method of design for flat slab systems of reinforced concrete which takes account of deflections of interior and exterior girders, and even of the bending moments of columns. To be sure, it is more or less approximate, and the final result is secured through a method of continued approximations. Mr. Goodrich.

* New York City.

Mr. Goodrich.

A start is made with the same assumptions as those by Mr. Janni, that a rectangular slab may be divided into a system of beams at right angles to each other. The live and dead loads are assumed to be concentrated at the intersections of the beams of the two systems. Simultaneous equations have been developed giving the proportional loads supported on each beam of each system computed on the basis of the relative deflections of the several beams and the fact that the total load carried by the two systems must be the total load on the structure.

This method ignores the deformation caused by shear, and all lateral dilation, as measured by Poisson's ratio. Designs have been worked out which include: beams rigidly supported; beams with supports subject to settlement or deflection; beams with settled supports in which the tangent remains at a constant or a changing angle, etc., etc.

It is believed that Mr. Janni has done a service to the Profession by calling attention to the necessity of considering the deflection of supports in ordinary problems of design.

Mr. Jonson.

ERNST F. JONSON,* ASSOC. M. AM. SOC. C. E. (by letter).—The author calls attention to two facts which are not generally recognized, *viz.*, that the deflection of the girders and Poisson's ratio enter as determining factors into the calculation of concrete slabs reinforced in two directions. Unfortunately, however, he ignores several equally, or even more, important facts, so that his treatment of the problem can by no means be regarded as a solution. These ignored facts are the following:

The distance, $d\ k$, to the neutral axis of a reinforced concrete beam is not a constant if the concrete shrinks during hardening and drying, and practically all concrete does. The value of k becomes then a function of the moment (unfortunately, a very complex function), varying from 0 for $M = 0$ to the usually assumed values when the moment reaches its maximum. From this fact it follows, of course, that the moment of inertia is not only a constant, but also a function of the moment, decreasing about 50% in value from zero moment to maximum moment. The consequence of this condition, again, is that the theorem of three moments cannot be applied to reinforced concrete, nor any other method which deals in deflection components. The author's method, therefore, is fundamentally erroneous, and so are all calculations of statically indeterminate structures of reinforced concrete. All reinforced concrete construction is statically indeterminate with regard to the stresses, but, in speaking of statically indeterminate construction, the writer means to refer only to cases in which the loads and moments are also statically indeterminate.

* New York City.

Mr. Jonson.

In a reinforced concrete slab, the moment of inertia cannot be assumed to be the same in both directions, as is done by the author, because economy demands that less reinforcement be used longitudinally than transversely, and because the two sets of reinforcement cannot be placed on the same level.

The author's method implies the assumption that all moments are at a maximum when the entire floor is covered by the live load. This assumption is erroneous. The moment in the center of the slab is a maximum when the adjoining slabs carry no live load, and the moments over the girders reach their maximum when the live load covers the two panels between which the girders run, but not the adjoining ones.

As the slab is regarded as having fixed edges, its flexure must be one of reversed curvature. The law of variation of loading, therefore, is more closely approximated by a straight line from end to middle than by a parabola, as assumed by the author. The latter would be the proper approximation for a non-continuous slab merely supported along its edges.

All calculations of reinforced concrete made on the assumption that the ratio, n or E divided by E_c, is a constant are unreliable, because this ratio varies with the time the load is applied, from an initial value somewhat less than that usually assumed to a final value about twice as great as that generally used in reinforced concrete calculations.

It is a question whether enough is known about Poisson's ratio of concrete to justify its use as a constant in a calculation of stresses in reinforced concrete. Short-time tests have given values of from 0.25 to 0.2, but it is not known how much its value might be reduced by prolonged application of load. It may probably fall to 0.1, or even less.

The statement on page 1690 that "these beams, a and b, are carrying the same uniform load" is erroneous. The author probably intended to say, "because the beams, a and b, deflect the same, although their lengths are different, they cannot carry the same load."

The author's statement, that when the length is great enough to make $\alpha = 1$ there is no advantage in two-way reinforcement, is misleading, because it implies that there is an advantage in such reinforcement when the length is less. According to the author's method of figuring, even in the most favorable case, *viz.*, the one in which the slab is square, it requires about one-third more reinforcement than a slab reinforced in one direction only. This excess might indeed be reduced by increasing the spacing of the rods toward the edges, but, within the limits fixed by the building law, this could not be carried far enough to produce economy. It would seem, therefore, that when the author says that the advantage of two-way reinforcement is maximum when the slab is square, he should say that the disadvantage is a minimum. The most desirable form of two-way reinforcement would

Mr. Jonson.

seem to be the so-called flat-slab construction which gives a flat ceiling and requires less form work.

In looking into this problem, the writer finds that the entire theory of reinforced concrete is rather crude, probably owing to the circumstance that, when it was worked out, the properties of concrete were not sufficiently well known to make a reasonably correct theory possible. The theory of flexure of concrete is especially in need of a thorough revision. The present theory is merely an adaptation of the theory of flexure of elastic solids to a material which is subject to permanent deformations several hundred per cent. greater than its elastic deformations. Time has not permitted the writer to make such a revision in the present discussion, but he has attempted to indicate its general direction. Before such a revision can be completed, more exact determination must be made of the physical properties of concrete, *viz.*, the true modulus of elasticity, the non-elastic deformation, Poisson's ratio, initial shrinkage during hardening, and subsequent expansion and shrinkage due to variations in absorbed water. In determining these values, the influences of proportions of mixture, wetness of mix, kind, size, and grading of aggregate, age of concrete, degree of wetness during hardening, time of application of load, horizontal or vertical direction of stress, previous loading, etc., must be taken into account.

The great influence which the shrinkage has on the flexure of a reinforced concrete beam calls for the following revision of the formulas. Unless it is immersed in water, concrete shrinks during hardening. This shrinkage may amount to 0.05 of 1 per cent. When concrete is saturated with water, it again expands. This shrinkage, m, has considerable influence both on the resistance and the deflection of a beam. If a concrete beam reinforced in the bottom only is supported by the forms until all the shrinkage has taken place, either the concrete will be in tension and the steel in compression, or the concrete will crack. It is on the safe side to assume the latter. If, then, the forms are lowered slightly, but not enough to cause the beam to carry its own weight, the cracks will close at the top of the beam. When the forms are removed entirely, the concrete in the top of the beam will compress, so as to allow a part of the crack to close until the compressive stress developed in the closed part of the crack multiplied by its leverage, $d\ j$, about the center of the reinforcement is equal to the bending moment produced by the load. It may be seen from the strain diagram (Fig. 3) that:

$$\frac{\frac{f_c n}{E}}{\frac{f_s}{E} + m} = \frac{k}{1 - k} \qquad (1)$$

Mr. Jonson.

and that, therefore,

$$k = \frac{f_c\, n}{f_s + f_c\, n + E\, m} \quad \ldots\ldots (2)$$

and, also, that

$$\frac{f_c\, k}{2} = f_s\, p \quad \ldots\ldots (3)$$

$$f_c = \frac{2\, f_s\, p}{k} \quad \ldots\ldots (4)$$

p being the steel ratio, which, therefore, is

$$p = \frac{f_c\, k}{2\, f_s} \quad \ldots\ldots (5)$$

Inserting this value of f_c in Equation (1), we have

$$\frac{2\, f_s\, n\, p}{k\,(f_s + E\, m)} = \frac{k}{1 - k} \quad \ldots\ldots (6)$$

$$k = \sqrt{\left(\frac{f_s\, n\, p}{f_s + E\, m}\right)^2 + \frac{2 f_s\, n\, p}{f_s + E\, m}} - \frac{f_s\, n\, p}{f_s + E\, m} \quad \ldots\ldots (7)$$

and also from Equation (6), that

$$f_s = \frac{E\, k^2\, m}{2\, n\, p\, (1 - k) - k^2} \quad \ldots\ldots (8)$$

$$f_c = \frac{2\, E\, k\, m\, p}{2\, n\, p\, (1 - k) - k^2} \quad \ldots\ldots (9)$$

From Fig. 3 it will also be seen that the reacting moment is

$$M = f_s\, b\, d^2\, j\, p = f_c\, \frac{b\, d^2\, j\, k}{2} \quad \ldots\ldots (10)$$

With regard to the maximum moment on a beam, the values of f_s and f_c are fixed, and from these follow those of j, k, and p. In 1:2:4 concrete, the value of $E\, m$ may vary from — 3 000 to 15 000, and that of n from 10 to 30. Hence, if the working stresses are 16 000 for steel and 650 for concrete, the steel ratio, p, may vary between the following limits:

$E\, m$	n	k	p
—3 000	10	0.333	0.675%
—3 000	30	0.600	1.218%
15 000	10	0.174	0.355%
15 000	30	0.386	0.784%

The greatest steel ratio is required, therefore, when the concrete is kept so wet that it expands slightly during hardening instead of shrinking. All concrete which is allowed to harden in air and finally dry out

Mr. Jonson.

shrinks more or less, according to the rapidity with which it is allowed to dry. Tests should be made to determine the minimum shrinkage which may be definitely counted on. In the meantime, 3 000 may be assumed as a safe minimum value for $E\,m$, which makes:

$E\,m$	n	k	p
3 000	10	0.255	0.52%
3 000	30	0.507	1.03%

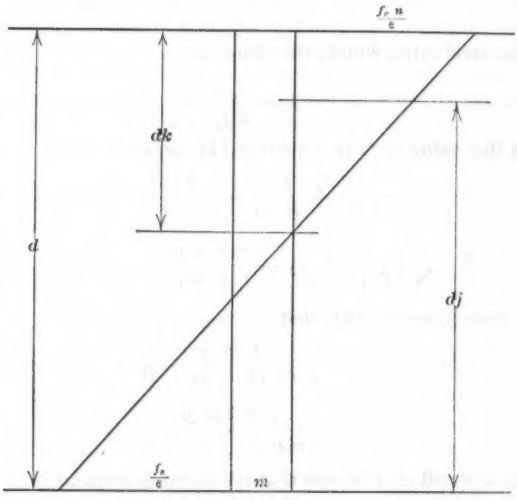

FIG. 3.

The value of $j\,p$ then varies between the limits:

$E\,m$	n	p	j	$j\,p$
—3 000	10	1.22%	0.889	1.086%
—3 000	30	1.22%	0.800	0.977%
+3 000	10	1.03%	0.915	0.944%
+3 000	30	1.03%	0.831	0.857%
15 000	10	1.22%	0.942	1.150%
15 000	30	1.22%	0.871	1.063%
15 000	10	1.03%	0.942	0.972%
15 000	30	1.03%	0.871	0.897%

This shows that for each steel ratio the strength of a beam increases slightly as it shrinks, but the effect is not marked, the main effect of the shrinkage being felt in determining the steel ratio. The strength also decreases slightly as the permanent set increases, but here, also, the main effect is on the steel ratio. A beam figured by the current

Mr. Jonson.

method would require a steel ratio of 0.77% instead of from 1.03 to 1.22%, as it should be, and would give a resistance, jp, of 0.67%, whereas, if figured by the correct formula, the resistance is only 0.62% for a beam kept wet and 0.64% for one hardened under ordinary conditions.

If the correct steel ratio had been used, the strength would have been increased in proportion. In other words, the current method exaggerates the stress on the concrete. Instead of 650 lb. per sq. in., as assumed, there is only 525 lb. It is natural that the continued yielding should reduce the unit stress by increasing the distance to the neutral axis. The higher unit stress which exists for a few hours after applying the load can do no harm, because it is relieved by the yielding of the concrete. On the other hand, the stress on the steel is, of course, correspondingly under-estimated, being actually 16 800 instead of 16 000 as figured.

Tests made by Mr. E. B. Smith, of the U. S. Office of Public Roads, have shown that 1:2:4 concrete stressed to 700 lb. per sq. in. had a modulus of deformation of 2 800 000 lb. per sq. in. immediately after the load was applied, but that this modulus changed its value as follows: in 1 hour to 2 600 000; in 24 hours to 2 000 000; and in 21 days to 1 400 000. A test made by Mr. C. M. Montgomery* in the Laboratory of the New York Board of Water Supply, confirmed these results in a general way. This test was made on a cylinder, 8 in. in diameter and 16 in. high, of about 1:2:4 mix, several years old, and thoroughly air-dried. The unit load was 300 lb. per sq. in. The modulus of elasticity maintained a constant value of about 3 000 000 ($n = 10$), but the total deformation did not become constant until the load had been on for 10 days. The modulus of total deformation, F, varied as follows:

	F.	n.
Initial	3 000 000	10
After 17 hours	1 800 000	17
After 2 days	1 600 000	19
After 4 days	1 300 000	23
After 7 days	1 200 000	25
After 10 days	1 100 000	27

Mr. F. R. McMillan, of the University of Minnesota, in his paper on "Shrinkage and Time Effects in Reinforced Concrete", gives further confirmation of these facts.

The deflection of a beam is due to the curvature which results from the stretching of the fibers on one side of the neutral axis and the corresponding compression of those on the other side. The angle of

* See Mr. Montgomery's discussion, p. 1712.

Mr. Jonson.

inclination thus produced in a very small part of the length, dx, is, therefore,

$$\frac{f_c\, n + f_s + E\, m}{E\, d}\, d\, x \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

and, hence, if x is taken as the distance to the free end of a cantilever, the deflection is

$$D = \int_o^l \frac{f_c\, n + f_s + E\, m}{E\, d} \times d\, x \ldots\ldots\ldots\ldots (12)$$

The moment on the beam may be expressed in terms of k, as follows:

$$M = f_s\, b\, d^2\, j\, p = \frac{E\, b\, d^2\, k\, m\, p \left(1 - \frac{k}{3}\right)}{2\, n\, p\, (1 - k) - k^2} \ldots\ldots\ldots\ldots (13)$$

If a diagram is constructed in which the values of k are the abscissas, and the ordinates of two curves, respectively, represent the corresponding values of

$$\frac{M}{E\, b\, d^2\, m}, \text{ and } f_c\, n + f_s + E\, m,$$

the value of the latter function which corresponds to a known value of the former may thus be found in a practical manner. If these values are utilized as ordinates in constructing a diagram on the beam, similar to an ordinary moment diagram, the summation required by Equation (12) may be accomplished by treating this diagram as if it were a diagram of a distributed load, the moment of which is wanted about the free end. The free end ordinate thus obtained is equal to

$$\int_o^l (f_c\, n + f_s + E\, m) \times d\, x \ldots\ldots\ldots\ldots\ldots (14)$$

In this way the deflection of any beam subject to statically determinate moments may be found. The middle deflection of a beam supported at both ends is found by treating each half as if it were a cantilever and taking the average of the deflections of these. The deflection of any point may be found by this method, if the two end deflections are plotted and then the proportionate deflection found at the dividing point.

The curve of flexure may be constructed by a graphic solution of the equation

$$y = \int_x^l \frac{f_c\, n + f_s + E\, m}{E\, d} (x - x_1)\, d\, x \ldots\ldots\ldots\ldots (15)$$

x_1 being the abscissa corresponding to y.

The calculation of a statically indeterminate construction by the foregoing method would be exceedingly laborious, but, fortunately,

Mr. Jonson.

such forms of construction are very rare in reinforced concrete. Most cases which are treated as indeterminate are not indeterminate at all. Take, for instance, the case of a continuous floor girder extending from one side of a building to the other, a total length of 60 ft., and supported by two columns each 5 ft. from the center. At a point 4 ft. from the column, the reinforcement is carried down from the top to the bottom of the girder. On one side of this point only positive moments are resisted and on the other only negative ones; hence, at the point where the reinforcement crosses the center line, the moment must be zero. The correct method of calculating such a girder is much simpler than by the illegitimate use of the theorem of three or of four moments.* Construct a static moment diagram on each span as if it were discontinuous. Then divide the diagram of the long span by a straight line in such a way that the positive moment at the middle of the suspended span is numerically equal to the negative moment in the double cantilever over the column. Then draw a horizontal line representing the negative moment across the middle span, and the area included between this line and the first moment curve will be the true moment diagram. The point at which the first straight line intersects the moment curve of the side span is, of course, the point at which the reinforcement should cross the center line. Likewise, any other case may be resolved into a system of cantilevers and suspended spans. The only truly indeterminate cases are those in which both the top and the bottom of the beam are reinforced. This is a form of construction which should be avoided on account of the difficulty of calculating it correctly. For the same reason, slabs reinforced in two directions should also generally be avoided, unless the slab can be made square and the problem thus simplified.

When the foregoing observations are applied to the author's problem, it resolves itself into the simpler problem of calculating a cantilever slab extending from each side of the girders and supporting a central suspended panel. If the edges were securely fixed, the projection of the cantilever might be made about 15% of the span, but if the torsional resistance of the girder has to be depended on to carry the live load of one panel when the adjoining panels are not loaded, it would probably have to be less. We have then the problem of finding such a value of the author's coefficient, α, and of a coefficient, β, as shall make the center deflection of the slab the same when figured longitudinally as when figured transversely. When the slab is supported on deflecting girders there enters into the problem also a coefficient, β, representing the percentage of the load which is carried by

* The theorem of four moments is the general form which applies to all cases; the theorem of three moments is applicable only when the two middle moments are of the same magnitude, which they generally are not when the girder is stiffly connected to the columns. See "The Theory of Frameworks with Rectangular Panels," by Ernst F. Jonson, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LV., p. 413.

Mr. Jonson.

the beam at its point of support on the girder. The reinforcement in the other direction may carry a part of the live load at this point. This coefficient, β, should be found before α by assuming values of α and β, and then figuring the corresponding deflections of the girder and the beam next to it, which must be equal if the assumptions are correct. In figuring the deflections for the purpose of finding the transverse moments, the longitudinal girders should carry a balanced live load, but the transverse ones should carry no live load on the panel on the other side. In this case, not only the deflection of the girder must be taken into account, but also that of the edge of the cantilever slab due to the twisting of the girder which results from the absence of live load on one side. When figuring with the α and β which give the greatest longitudinal stress, the conditions, of course, are reversed.

It is evident that a direct solution of this problem is impossible, for it is necessary to start with assumed values of α and β, which must be corrected if the deflections do not turn out to be equal in both directions. The influence of lateral strain may be taken account of by adding an imaginary negative load of such magnitude that the strain which it would produce in the concrete is equal to the lateral strain due to the total loading (including the imaginary negative load) on the beam in the other direction; but, in figuring the deflection due to this load, the strain in the reinforced side must be ignored, for Poisson's ratio cannot be applied to the tension side. A reasonably true solution of this problem is thus seen to be very laborious, but if it is worth while solving at all it is worth doing it right. Tables and diagrams may be constructed for practical use.

The initial stress in a reinforced concrete column due to shrinkage is as follows, f_i being the tension in the concrete and f_r the compression in the steel:

$$f_i = f_r p$$

$$\frac{f_i n}{E} + \frac{f_r}{E} = m$$

$$f_r = \frac{E m}{p n + 1}$$

$$f_i = \frac{E m p}{p n + 1}$$

These stresses must be added to those due to load and wind. Owing to the general predominance of compressive stress, it makes no practical difference whether or not the concrete cracks. In a column with $p = 4$, and 400 lb. per sq. in. on the concrete—as favorable a case as may be found in current practice—the stress in the steel is

$$f_s = 6\,800 + 8\,700 = 15\,500.$$

Mr. Jonson.

If, on the other hand, $p = 0.5$, and the load on the concrete is 500 lb. per sq. in., then

$$f_s = 13\,000 + 14\,000 = 27\,000.$$

This means that, with the current method of figuring, unless a considerable percentage of reinforcement or a low working stress on the concrete is used, the steel is stressed nearly to its elastic limit. On the other hand, the concrete is not stressed very high, such stresses, corresponding to the foregoing cases, being, respectively,

$$f_c = 290 - 272 = -\ 18$$
$$f_c = 468 - \ 65 = \ 403$$

The correct method of calculating a reinforced concrete column, therefore, would be one which takes account of the shrinkage stresses That is,

$$f_s = f_y + \frac{E\,m}{p\,n + 1}$$

$$f_x\,n = f_y$$

f_x being the available working stress on the concrete and f_y that on the steel. As this formula gives f_y its minimum value for the maximum value of m, $E\,m$ must be given the value 15 000. If $f_s = 20\,000$, we have

$$20\,000 - \frac{15\,000}{30\,p + 1} = f_y$$

$$f_x = \frac{f_y}{n}$$

$$f_c = f_x - \frac{E\,m\,p}{p\,n + 1}.$$

We get then for extreme values of p:

p	f_y	f_x	f_c
4%	13 200	440	167
½%	7 000	233	168

which shows that the concrete is never stressed high in columns, and, for this reason, a rather high stress may be used on the steel.

In working out the foregoing discussion the writer was largely led away from the special problem of Mr. Janni's paper by the discovery that the generally accepted assumptions of reinforced concrete theory do not correspond with the facts. The solution of the problems raised by this discovery have been indicated in the foregoing discussion in a general way only. The fuller working out of the theory of reinforced concrete in accordance with the facts will be made the subject of a future paper. The foregoing discussion must not therefore be taken as the writer's well established and final conclusions, but rather as a step toward the elimination of certain fundamental errors in the theory of reinforced concrete.

Mr. Montgomery.

CHARLES M. MONTGOMERY,* ESQ. (by letter).—The following is a record of a test made in the Laboratory of the New York Board of Water Supply, in connection with the discussion of Mr. Janni's paper by Mr. Ernst F. Jonson. The specimen was a cylinder, 8 in. in diameter and 16 in. high, made at one of the tunnels of the Catskill Aqueduct, from concrete used for lining the tunnel, the mix of which was approximately 1:2:4. The specimen was made about 4 years ago, and was stored in damp sand until May, 1915, since which time it has been exposed to the air. The coarse aggregate was Fordham gneiss of 2 in. maximum size; the fine aggregate was also Fordham gneiss. The crushing strength was 3 550 lb. per sq. in.

A narrow iron collar was bolted around each end of the specimen (with a measuring point projecting on each side). The distance from center to center of collars was 15 in. This specimen was not made for the purpose of determining deformations, and was therefore deficient in length. The nearness of the collars to the ends undoubtedly reduced the deformation, so that the modulus of elasticity given by this test is probably somewhat high. The purpose, however, was not to establish the value of the modulus of elasticity, but to discover to what extent deformations would continue during

* Inspector, Board of Water Supply, New York City.

a prolonged application of the load. The deformations were measured by two inside micrometers, reading to 0.0001 in., which remained in place during the entire period of the test. The contact between the micrometer and the upper measuring point was indicated by an electric buzzer. The initial load was 10, and the final load 300 lb. per sq. in. Table 1 is a record of the test. Mr. Montgomery.

C. A. P. TURNER,* M. AM. SOC. C. E. (by letter).—This paper undertakes to treat the flat plate or slab from the standpoint of the theory of work. It makes the work dependent on Poisson's ratio and moments in selected strips across the center portion of that plate. Mr. Turner.

It is fundamental to the theory that the amount of work done depends on the deflection. Now, a formula which involves work must be such that the deflection can be computed and checked with observed deflection. Otherwise, there is something wrong with the formula, but the author has apparently made no attempt to check his theory by observation. Therefore, it lacks confirmation.

Suppose we compare a circular plate supported at its center with a double cantilever beam supported at the middle. The resisting moment in the cantilever causes stresses along its length, and Poisson's ratio may be disregarded, as it has no effect on the resulting deflection, in accordance with the fundamental equations of extensional stress and strain established a generation ago and accepted by Grashof and all authorities on the subject since then. These equations are as follows:

$$Ee_1 = p_1 - Kp_2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

$$Ee_2 = p_2 - Kp_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which K designates Poisson's ratio, p_1 and p_2 are the external applied or apparent stresses per unit of area of cross-section of the plate, which act parallel to the axes of x and y, respectively, if these latter lie in the neutral line of the plate, and e_1 and e_2 are extensional elongations of the plate per unit of length parallel to x and y, respectively. Hence, if p_2 is zero, as it would be in a beam, $Ee_1 = p_1$, the longitudinal deformation, e_1, depends solely on p_1, and determines the deflection.

Thus it is evident that K cannot affect the internal work in a beam in a manner comparable to its effect in a slab, yet Mr. Janni proposes to introduce K into what is substantially a beam formula.

From the mathematical standpoint, Mr. Janni does not work correctly from the general fundamental equations of extensional stress and strain. In deriving his equations for the true moment of the strip parallel to the axis of x, he assumes $p_2 = 0$. In deriving his equation for the strip parallel to the axis of y, he assumes $p_1 = 0$, and, in Equations (1) and (2), if p_1 and p_2 are zero, then the Poisson

* Minneapolis, Minn.

Mr. Turner.

ratio is eliminated; and yet, having eliminated the Poisson ratio and effect, Mr. Janni arbitrarily inserts a factor involving this ratio in his equation to represent the work which, on the basis of his strip assumption, in deriving his equations for the moment on the strip, has been eliminated. The terms inserted are correct neither for the beam theory nor for the plate theory.

Consider the case of a plate: The deformations due to spherical curvature or bending are radial and circumferential. Assuming that K (Poisson's ratio) is zero, it has been demonstrated* that the work done in a circular direction is equal to that done in a radial direction. Now, radial deformations alone determine the vertical position of the cantilever plate, and though the circumferential deformations necessarily accompany radial deformations, they provide a means of storage of energy which is not involved in nor determines the vertical deflection. Accordingly, in the circular cantilever plate, half the work is done in a manner which produces no deflection. In the slab supported on separated posts, we have a cantilever area about the post, and a suspended span, which is really an inverted plate similar to the cantilever portion about the column, located about the diagonal center of the span so that treatment of the plain cantilever serves for the treatment of the combination of the cantilever and suspended span in a diagonal direction, approximately.

We will now proceed to compare the double cantilever beam and the circular cantilever plate, assuming that the plate and beam have the same thickness, and the same metal, and that each stores an equal quantity of energy, Q; in which case:

Let W_1 = the load on the cantilever beam uniformly distributed;
W_2 = the load on the cantilever circular plate;
D_1 = the mean deflection of the load in the cantilever beam;
and D_2 = the mean deflection of the load on the cantilever plate.

Since, in the cantilever plate supported at the center, half the work is done in a manner which produces no deflection, as compared with a cantilever beam, the deflection would be reduced one-half. Now,

$$Q = \frac{1}{2} W_1 D_1 = \frac{1}{2} W_2 D_2;$$

but, the amount of energy stored being assumed as the same, W_2 must equal 2 W_1, since $D_2 = \frac{1}{2} D_1$. Now, if we assume the deflection the same, it is apparent that W_2 must equal 4 W_1; or, the work of deformation is four times as great in the double cantilever beam, strained in one direction, as it is in a circumferential plate, strained

* "Concrete-Steel Construction", by Eddy and Turner, pp. 137-138.

in two directions, for equal loads; and this is on the basis that there is no Poisson action, that there is no reduction of strain per unit of stress in one direction by another stress acting at right angles thereto. Mr. Turner.

Compare a reinforced concrete beam and reinforced concrete plate on posts with square panels, taking an interior panel uniformly loaded, for simplicity, to present the essential facts: The experimentally determined formula for deflection, for the old-style, mushroom, flat plate of concrete, may be written for a square panel as follows:

$$\Delta = \frac{W L^3}{2 \sqrt{2} \times 7\,000 A_s h^2} = \frac{W L^3}{19\,800 A_s h^2} \text{ (approximately).}$$

In this case, L is the diagonal of the panel and Δ is the deflection at the diagonal center. A_s is the steel area at mid-span and h is the distance from the center of the steel to the top of the concrete.

A similar formula, worked out from a number of experiments on thoroughly cured, continuous, concrete beams, integral with the slab, these beams being about 12 in. wide and from 18 to 24 in. deep, with a 6- to 8-in. slab and from 15 to 24 ft. from center to center, is:

$$\Delta = \frac{W L^3}{5\,000 A_s h^2};$$

in which A_s is the cross-section of the steel at mid-span and h is the distance from the center of the steel to the top of the concrete.

Comparing these formulas, it will be seen that the diagonal deflection of the slab is substantially one-quarter of that of the continuous beam at mid-span, a result in keeping closely with the theory of work above outlined, except that the slab, being integral with the beam, reduces its deflection.

For simple beams, the writer deduced, and published in 1909, a formula in which the coefficient is taken as the reciprocal of 850. Now, the relative stiffness of the continuous and simple beam is known by theory to be as five to one, so that, from these considerations of numerous experimental results, it would appear that the slab integral with the continuous beam has increased its stiffness approximately 18 per cent. The Poisson effect which Eddy finds in his theory is a little greater than this, increasing the stiffness 33 per cent. The simple beams experimented on did not have true knife-edge supports, and this discrepancy would be expected for that reason.

The question, "what is the nature of the Poisson effect in reinforced concrete"?, may be here considered.

Reinforced concrete is not a homogeneous material, but a composite of steel and concrete combined. There can be no molecular

Mr. Turner.

action, such as is found in a homogeneous material. The lines of stress, however, may be represented somewhat as are the variations of shade and shadow in a copper half-tone plate. The picture is thrown on the plate through a screen. Shade and shadow are not continuous but are interrupted, and, if the interruptions are sufficiently fine-grained, the appearance to the eye and the general effect is that of the photograph.

So with reinforcement, if we are to imitate homogeneous material, we must have the reinforcement distributed so that the resulting structure is relatively fine-grained. It is on this principle that the imitation of a homogeneous plate may be made. The distribution of the stress and the manner in which the stress in one direction may co-act with that in another has been discussed at length.* The object of this short discussion is to point out the theoretical error involved in the supposition that work, where there is double curvature, is measured largely by the Poisson effect. Poisson effect or action enters into the problem as a relatively minor factor, a matter which Mr. Janni has not discovered, because he has tried to compare beam strips and work through this Poisson coefficient and get at the external work, something which is not possible in working from strips, as the writer pointed out from comparison of the double linear cantilever and the circumferential cantilever.

Much of the difference of opinion among the Engineering Profession to-day regarding beam action and imitation of plate action in concrete may be accounted for through the failure of the Profession generally to understand the theory of work in its relation to horizontal shearing rigidity and flange rigidity.

If we have two planks, for example, placed one upon the other, and load them, the stiffness and strength is substantially the aggregate of the two planks, because the friction between them would ordinarily be very small, and the upper corner of the lower plank would slide by the lower corner of the upper plank, if they were of the same length. Now, by bolting and gluing these planks rigidly together, we increase the stiffness fourfold and the strength twofold, because we prevent this sliding one upon the other. The result produced by the resistance of this shearing rigidity at the neutral plane of the beam or slab becomes apparent.

If we test a slab which, though hard on the outside is not thoroughly cured at the neutral plane, there is no proportionality at all between the flange stresses and the deflection. If, however, we allow the slab to become thoroughly cured, and compare work which is thoroughly hardened and rigid throughout, then, under these circumstances, we find the most gratifying concordance between relative deflections and stresses.

* "Concrete-Steel Construction", by Eddy and Turner.

Mr. Turner.

Initial loading, however, involves some allowance for the shrinkage and temperature stress of hardening. If we are to measure stresses in the concrete of slabs and beams when first loaded, even though they are thoroughly cured, the deformations in the concrete compared should be those of the recovery after the initial loading, and not the initial deformation which includes the effect of the load plus that of temperature and shrinkage stresses in hardening. In subsequent loadings, or after one or two repeated loadings, almost perfect elasticity will be found, but the effect of shrinkage and temperature stresses is more local than general in the slab, and the deflections and steel stresses can be computed accurately with ordinary concrete executed with ordinary care when the work is thoroughly cured and hardened.

Much conscientious hard work in investigating concrete is of no value whatever, because investigators have failed to appreciate the fact that cured concrete is the only kind on which it is worth while to make measurements, because it is the only kind of concrete in which there is a definite relation between the deflection and the amount of load, and consequently the only kind to which mathematical theory of any kind is applicable. Just as sure as concrete is only partly cured along the neutral plane, although hard on the outside, there is no relation between deflection and stress which we have any theory capable of computing, and our measurements then are of no value except in showing what may occur in a slab at this exact stage of hardening, and to duplicate this stage or know that two concrete specimens have reached exactly the same stage of partial curing is something no one has been able to do as yet; hence the measurements made are of academic value only.

Another matter which is very puzzling to many is the fact that the mechanics of a solid is such that ordinary rules of statics do not apply, that is, the rules of statics as applied to the separate members of framed structures are not here applicable. For example, under pure statics, a force in one direction cannot affect the magnitude of the force at right angles thereto. In other words, it has no component which affects it according to statics; but, in the mechanics of a solid, that is not the case. A deformation in one direction under a given force affects and influences the deformation produced by a force at right angles thereto, and it may thus reduce the work done by the external forces to the surprising amount of 80 per cent.

Failure to understand these elementary relations has caused many building departments to adopt irrational regulations, thereby placing a premium on more dangerous types of construction and putting at a disadvantage the more rational and safer types of design.

The difference between beam resistance and slab resistance is, in part, that in the beam horizontal shearing stresses act only in horizontal planes, but in the slab, with its double change in curvature, horizontal

Mr. Turner.

shearing forces act in vertical planes as well. Now, the action of these latter forces is disregarded in any beam strip theory, a fact recognized in the classical theory of plates for fifty years. Early flat-plate theories did not take into consideration the Poisson effect at all, a fact which Mr. Janni and many present-day engineers apparently have overlooked.

Mr. Janni assumes that putting an arbitrary factor involving Poisson's ratio into a beam formula makes it apply to a plate. The magnitude of this error may be found by computing the deflection by his theory and comparing the computed values with the experimentally determined deflection.

Working on the basis of beam theory in the design of flat slabs, the quantity of steel used frequently overbalances the strength of the concrete, and unsatisfactory work frequently results. The comprehensive theory, which takes into consideration properly the double curvature and twisting of the plate, whether it is supported on four sides or on a series of posts, will insure the avoidance of this undesirable kind of design. The idea that the Poisson effect in a reinforced concrete slab is a property either of the concrete or of the steel is erroneous. The mathematical coefficient applies to true molecular phenomena. The imitation of that phenomenon in a fine-grained composite structure has no direct relation to a plate, either of uniform concrete or of homogeneous steel.

Another error, which it appears to the writer has crept into many discussions, is the idea that Poisson's ratio is a constant. Its value would seem to depend entirely on the shape of the piece tested, and be a constant for the same kind and shape of test piece, but not for different kinds and different shapes. A square bar would give one value; a wide rectangular bar would give two values under tensile stress; a plain flat plate bent in one direction gives no criterion as to the Poisson effect in a plate bent in two directions under the fundamental equations of stress and strain.

The magnitude of the Poisson effect may be readily shown from the fundamental equations of internal stress and strain—Equations (1) and (2)—to be a maximum when $p_1 = p_2$. In other words, it requires equality of stress in the direction of x and y, respectively, for the maximum efficiency. The previous demonstration of the action of the circumferential cantilever plate is based on this equality, for when the forces along x are greater than those along y, circumferential deformations enter into the deflection largely along x. Hence, the Poisson effect, as well as the effect of double curvature, varies between square and rectangular panels according to the law of this variation. This law is found experimentally to indicate that, in a rectangular panel, the length to be considered is not a mean of the two sides, but is that of the longer side, a relation which holds good with panels in which the width is six-tenths of the longer side. The diagonal length

from column to column cannot be used in a rectangular panel, and for that reason the empirical formula for deflection published in 1909 by the writer was confined to the use of the direct span from column to column, using the longer side of the rectangular panel. Mr. Turner.

Regarding the shrinkage of concrete in columns, this, in the writer's judgment, is a matter which should be given more consideration than is usually accorded it. If the column is well tied in, 12 000 lb. per sq. in. on the steel, if it is hard, should be permissible, provided that the column bars are lapped and not butted. Lapping permits an adjustment during the curing stage which is not possible if the bars are butted. Tests show higher values where the longitudinal steel does not abut the face-plate of the testing machine.

No engineer who has loaded a plain concrete plate and witnessed its performance under a drop of temperature of 25° could rationally talk of the evanescent value of the tensile strength of concrete. In practical construction, the splice or joint eliminates this resistance; still, the deflection is increased but little, and the steel stress likewise undergoes little change. This observation and experience indicate the magnitude of the error involved in Mr. Godfrey's conception of the problem.

Mr. Godfrey has stated that "Tests ought to be made by the Federal Government, not by patent owners, interpreted by their hired experts." His contention, however, is fallacious, and this is shown clearly by the fact that the test of the Curran Building, in St. Louis, was conducted by Robert W. Hunt and Company, and that the report of that company cannot be regarded as unworthy of credence simply because it was made by paid experts. Mr. Godfrey should be informed that numerous articles in the technical press indicate the great extent to which deck mushroom floors have been adopted, in bridge work with columns from 30 to 40 ft. in length, and spans from 30 to nearly 50 ft. There are also many descriptions of tests of such floors; for instance, the floors of the Minneapolis Post Office were tested by the Federal Government.

As a result of the writer's observations, he is firmly convinced that in the past many engineers have attributed the increased rigidity of the work to the tensile strength of the concrete, instead of ascribing it to the increase in horizontal shearing rigidity along the neutral plane of the slab due to thorough curing. Satisfactory evidence of the truth of this fact may be readily brought out by testing a slab without reinforcement. The great importance of this shearing rigidity has been illustrated by the example of the two planks where it increases the stiffness fourfold and the strength twofold. Permitting horizontal shearing rigidity to become a factor in vertical planes has likewise a phenomenal effect on the resistance of the plate, an effect which is brought out only by the double curvature.

Mr. Turner.

It may be argued that the concrete matrix binds the steel and furnishes this shearing rigidity to a large extent. The error of this view will be obvious from the consideration of the example of the two planks which do not furnish the shearing rigidity of the bolts or the glue which increase the stiffness fourfold. Neither does the steel by itself nor the concrete by itself furnish the shearing rigidity of the composite structure. The action as a composite structure is due to bond stress, and bond stress is a shearing resistance added to the combination by the steel embedment and the shrinkage of the concrete in hardening about the steel. Thus, where steel is embedded in concrete we are dealing with a new element which has not been given proper consideration by those who fallaciously assume that the effect of the addition of this shearing rigidity is a property of the concrete. Were this a fact, reinforcement would be abandoned. If concrete can furnish three or four times the tensile resistance of the steel, wherein lies the utility of the steel? In order to account for slab phenomena, an explanation based on an unheard of tensile strength of concrete is offered, the absurdity of which becomes apparent only on analyzing the effect of horizontal shearing forces in horizontal planes and horizontal shearing forces in vertical planes. The erroneous idea that a mere Poisson coefficient accounts in fact for the great difference in performance of the slab and beam becomes evident when we reduce this coefficient to zero and find that the work of deformation for the same load is one-fourth as great with the circular cantilever plate as it is with the linear cantilever plate. No more forcible illustration of the action of the horizontal forces in vertical planes can be brought out than this explanation.

No more cogent reason can be offered for abandoning beam strip theory than the concordance of true theory with empirical, experimentally determined and proved, formulas for deflection.

Distribution of Stress.—The composite structure not only differs from the homogeneous plate in respect to the difference between it and the infinitesimally fine grain of the make-up of a homogeneous plate, but also differs in the distribution of resistance under the known law of the bond shear or bond stress. The action of these forces is most efficient where the horizontal shearing deformation is a maximum. This occurs toward the end of the cantilever on each side of the line of inflection in the flat slab supported on columns. Thus, there are differences between distribution of stress in the homogeneous plate and the imitation of the homogeneous plate.

The unique application of the mathematical flat-plate theory of Eddy is based on the assumption of an imaginary solid endowed with those imaginary properties which will produce the deflection of the composite plate. By this expedient Eddy succeeds in figuring the vertical geometry of the composite plate under load, that is, the

vertical geometry of the imaginary plate which fits or substantially agrees with that of the composite plate. Having determined this geometry, he has determined mathematically the geometry of deformation, and, reducing this geometry of deformation to stress, he is able to compute, with a high degree of precision, steel stresses and deflections in all recorded tests on thoroughly cured concrete plates. Thus, in one and the same theory, Eddy alone has succeeded in deriving equations by which the deflection and steel elongations are admitted by all to be computed in keeping with results of experiment. It seems to the writer that all criticism of Eddy's methods is based on an entire misapprehension of the stages by which they are derived, and a misunderstanding of the theory of work which, in its simplest and most elementary form, the writer has endeavored to present in the foregoing discussion. Mr. Turner.

Even in the reinforced concrete beam, it is too commonly assumed that there is a much closer analogy to homogeneous material than actually exists. In the reinforced concrete beam, horizontal shears in vertical planes are also to be found which do not exist in the homogeneous beam. Consequently, these shears which in the lower plane cause greater deformations close to the surface of the steel than between the bars, affect the amount of resistance required to hold the external loads in equilibrium at the center. Since it may be shown that the internal work of deformation in view of the bond stress is in part lateral, the energy there stored has a marked effect in reducing the deflection and the work of deformation, all erroneously attributed heretofore to an overestimated or imaginary direct tensile strength of the concrete. When the work of indirect stress is followed out, and a correct theory of the beam is presented, much of the difference of opinion among engineers on reinforced concrete will disappear.

Time Effect.

Rich Concrete.—Concrete grows more rigid with time, aside from shrinkage and temperature effects, but 90-day concrete of a 1:2:4 mix cured at a temperature greater than 65° shows little increase in deformation where the stress is not more than one-third of the ultimate. For greater stresses it shows a considerable and gradual increase in deformation with continuance of pressure, up to a certain limit, which must be considered in the correct interpretation of test results.

Lean Concrete.—In discussing time effects which occur during the curing of concrete, the properties of a standard 1:2:4, or rich, concrete should not be confused with those of a poorer concrete. In cases where, through ignorance or otherwise, buildings have been erected in which a concrete has been used consisting of a 1 cement to 6 bank run of gravel, when such a mix was no better than 1 cement to 5 sand, the quantity of cement is insufficient to fill the voids, and the concrete is

Mr. Turner. not solid. Its physical properties are then very different from that of a standard 1:2:4 mix. Such concrete will continue to deform with time to a surprising extent, without showing many noticeable cracks, and the process of sagging will continue apparently without definite limit for a period of several years. It is evident that such concrete should be avoided as wholly unfit for building purposes, as its characteristics are entirely different from those exhibited by a suitable mix, with which it should not be confused.

Mr. Eddy. HENRY T. EDDY,* ESQ. (by letter).—*1.—Fundamental Equations.*—In case the rectangular axes of x and y lie in the horizontal neutral plane, and z denotes the deflection of a flat slab or plate, it is known that the correct moment equations are†

$$\left.\begin{aligned}(1-K^2)\,M_1 &= \pm E\,I\left(\frac{d^2z}{dx^2}+K\frac{d^2z}{dy^2}\right)\\ (1-K^2)\;M_2 &= \pm E\,I\left(\frac{d^2z}{dy^2}+K\frac{d^2z}{dx^2}\right)\end{aligned}\right\}\quad\ldots\ldots\ldots(1)$$

in which, for convenience, K is used to express Poisson's ratio of lateral deformation, in place of the expression $\frac{1}{m}$, used by Mr. Janni, M_1 and M_2 are the apparent bending moments per unit of width of slab due to the applied forces or loads which tend to cause flexure of lines initially straight and drawn on the slab parallel to the axes of x and y, respectively.

These equations are substantially the same as those used by Grashof in his classical German treatise on the theory of elasticity and strength (1878), and copied in Lanza's American treatise on applied mechanics, which was used for many years, since about 1885, as a textbook at the Massachusetts Institute of Technology. They have been accepted universally as valid, and have never been disputed by any competent writer.

These equations are established by expressing the conditions for the statical equilibrium of an infinitesimal rectangular element of a plate or slab supporting an element of load and subjected on its vertical sides to vertical shearing stresses, and to the tensions and compressions arising from the bending moments as well as to the horizontal shears due to twisting moments. These comprise all the forces that can possibly act on the element, and the conditions for equilibrium are the sufficient and complete expressions for the exact solution of the problem in hand. Any other attempt less general than this must of necessity be, at most, more or less of a tentative approximation, if indeed it can be designated as any approximation

* Minneapolis, Minn.

† See "Concrete-Steel Construction", Eddy and Turner, Minneapolis, 1914, p. 173.

Mr. Eddy.

at all. So far as known, no such attempt has had any success in approximating to the actual stresses or deflections shown by tests; and the solution which has been derived from Equations (1) has been found to be in numerical agreement with all published tests and many others as yet not published.

Now, the fundamental equations used by Mr. Janni differ from these in reality only in one point, namely, by suppressing and leaving out the last term of each of them. That this is the fact, however, is not entirely apparent, at first view, because Mr. Janni in his mathematical work has chosen to develop the subject by attempting to modify and apply the equations of Professor Fraenkel for beams, which express the work performed during deflection by an assumed auxiliary force applied at the point where the deflection is measured. It may be readily shown, however, that Fraenkel's equations are equivalent to the ordinary equation of flexure of a beam as quoted by Mr. Godfrey, namely,

$$M = E \frac{d^2 z}{d x^2}.$$

When Mr. Janni says it is known that the expression for the work is given by his Equation (2), the writer feels compelled to say that the work in a slab or plate is not known to be expressed correctly by this Equation (2), because it is incompatible with the accepted Equations (1) given by the writer, besides other reasons which will be given later.

The only criticism that Mr. Godfrey makes of Mr. Janni's equations is that they involve such mathematical complications as to prevent most engineers from being able to judge of their correctness. He, himself, does not suggest that they are incorrect, and he is evidently not aware that they are incompatible with the ordinary equation of flexure which he quotes. His remarks, however, convey the impression that he had understood how they were established; but, since they are in fact not correct, Mr. Godfrey cannot have understood how they were derived mathematically.

It is possible to make this assertion of incompatibility between these equations with certainty, notwithstanding the fact that M in Equation (2) is the apparent moment of that part of the total load which Mr. Janni has arbitrarily taken as acting to produce M, while the M_1 in the writer's Equations (1) is due to the entire load, because Equations (1) enable us to determine the shearing stress per unit of width of the section where the bending moment is M_1, and Mr. Janni's arbitrary distribution of the total loading on each beam strip also determines the shearing stress in that strip. This last differs from that previously mentioned, therefore the systems are incompatible. What Mr. Janni has in effect done by his formulas is this:

Mr. Eddy.

First, he has reduced the deflection below that of a separate beam strip by assuming the entire load on the slab to be arbitrarily apportioned between the assumed beam strips, which cross each other at right angles parallel to the edges of the panel. Leaving out of account all question as to how this would agree or disagree with some other assumption—such, for example, as diagonal beam strips—the arbitrary subdivision of the loading between the two sets of strips cannot pretend, of course, to any mathematical accuracy, and would have to give way before any mathematically exact method. There is a much more accurate investigation of this kind of hypothesis due to Danusso and edited by von Bronneck* in German, on concrete slabs with crossed reinforcement, in which the strips have identical deflections at all points of crossing, instead of merely on the center strips, as proposed by Mr. Janni. Since the beam strips of Mr. Janni are not required to have identical deflections at any other points than along the middle strips of the panel, his method is necessarily insufficient to secure accurate results.

Secondly, Mr. Janni further reduces deflections by introducing the factor, $(1 - K^2)$, arbitrarily, so far as appears from anything in the paper. It may very well be the fact that this factor is involved in the correct equations, as it is in fact in the writer's Equations (1), but to attempt to take account of the effect on any given strip of the adjacent parallel strips by the insertion of this factor is entirely unwarranted unless the correctness of the procedure is otherwise established.

However, regardless of any question of these two attempted corrections of beam theory to make it apply to the beam strip theory of slabs, Mr. Janni has misunderstood and incorrectly used Fraenkel's equations of work and deflection in several particulars, for, in the first place, his Equation (1) is incorrect, and should read

$$d\,L = \frac{1}{2} D\,d\,F$$

because $d\,L$ is the elementary amount of work performed by the elementary force, $d\,F$, when it is gradually applied with the rest of the external load during the progress of the deflection, D.

Mr. Janni, in his Equation (1), has practically assumed that $d\,F$ is already acting on the beam before the rest of the external load is applied to it, whereas it is in fact a part of that load and subject to the same conditions as any other part of it. This alteration alone would change Mr. Janni's results by 100%, were the rest of the development correct.

* Ernst and Son, Berlin, 1913.

Mr. Eddy.

There is, however, another error involved in his Equation (2) by which the error in Equation (1) is nullified. This can best be appreciated by first considering the external moment, M:

Let M = the total external moment, including F, as given in Equation (4).

Let $\mathfrak{M}$ = the external moment, excluding F, as given in Equation (7).

Let $\mathfrak{m}$ = the moment of F.

Then $M = \mathfrak{M} + \mathfrak{m}$.

Now, in Equation (2), if we disregard the factor, $(1 - K^2)$, the work, L, should be that performed by F during the gradual application of the total load, but Equation (2) is written incorrectly, for it contains the factor, M^2, where it should have, in place of this, the widely different factor $M\,\mathfrak{m}$.

These errors in Equations (1) and (2) are curiously so related, the one to the other, that Equation (3) is the same as would be obtained were the alterations just pointed out made in Equations (1) and (2).

It appears, therefore, that Mr. Janni did not understand the true import of his Equations (1) and (2). Much confusion would be avoided in this paper were a careful distinction observed between the moments, M and $\mathfrak{M}$, as defined by Equations (4) and (7), since M is used in the paper for either the one or the other.

It follows, also, that Mr. Godfrey did not comprehend this matter any better, although he did not say so.

Furthermore, Mr. Janni has introduced the same two arbitrary reductions into the fundamental stress equation for beams that he had already attempted to introduce into his equations for work and deflection, for he states that "the general equation of stability given by theory" is

$$f\,\frac{I}{h} = (1 - K^2)\,M,$$

in which M is the external moment due to the arbitrary and inaccurately assumed external load on the strip, excluding F, while f is the stress in the steel and h is its distance from the neutral axis. There is, however, no proof of the fact that this equation is given by any known theory, although when $K = 0$, the equation is the correct ordinary equation of the stress, f, due to the applied moment, M.

In view of these two corrections, introduced by Mr. Janni into beam theory in his attempt to make it apply to beam strips, the question should be fully settled by him whether both these corrections are required at one and the same time, or whether he should use only one of them, and, in that case, which one is required. He could, perhaps, settle that question by comparing his results with test data. It is not probable, however, that either or both of these corrections will bring the theory into good agreement with observed

Mr. Eddy.

results. Unless more secure foundations can be established for Mr. Janni's mathematical superstructure than appear in this paper, no great confidence can be put in the substantial validity and accuracy of his conclusions.

2.—Shrinkage, Time Effects, and Variation of the Modulus of Concrete with the Stress, etc.—The conclusions of Mr. Jonson are self-evidently incorrect, because it appears, from his Equations (8) and (9), that f_s and f_c, which he finds to be proportional to m, would vanish in case $m = 0$, a case which he himself admits might occur were the concrete kept wet during the process of curing. These absurd results are due to the fact that his Fig. 3 does not represent correctly the relations under consideration.

These formulas have reference to the theory and design of reinforced concrete beams, a subject which has received more careful theoretical and experimental attention than would be implied from Mr. Jonson's remarks, which also intimate that he does not regard himself as having done more than indicate the path along which a radical revision of the theory now current should proceed, a theory on which many eminent engineers have spent their very best efforts. The failure of his Equations (8) and (9) make it evident that his indications are incorrect.

The writer finds himself unable to agree in ascribing any such controlling effect on the theory of beams to shrinkage as Mr. Jonson thinks occurs.

Recourse is to be had in all such matters to scientific experiment and observation, and the object of any theory is to give a rational explanation and co-ordination of the observed facts. Perhaps the largest single body of well-ascertained data on reinforced beams is found in Technological Paper No. 2, Bureau of Standards, which reports the tests on 333 beams, 8 in. wide, 11 in. deep, 13 ft. long, and 12 ft. span, loaded at the one-third points, and with percentages of reinforcement varying from 0.5 to 2 per cent. The gauge length was 29.25 in. Four different kinds of concrete were used, cinder, gravel, broken limestone, and broken granite.

The one noticeable and unmistakable phenomenon of the last three kinds of beam is shown in the graphs in which the abscissas represent the elongations or stresses in the steel at mid span, and in which the ordinates represent either $\frac{M}{b\,d^2}$, or the load, according to the scale used. All these graphs have a pronounced knee at a unit steel stress of about 5 000 lb., and are in general shape like those found in tension tests of a steel rod at the yield point. The tests of cinder-concrete beams also yield similar results, but lack to some extent the sharply defined definite shapes of those just mentioned. Between unit stresses

of 6 000 and 30 000 lb., the graph has practically a uniform slope. The elastic limit of the steel used was from 33 000 to 41 000 lb., and its ultimate strength was between 52 000 and 64 000 lb. The working and test stresses, therefore, lay between 6 000 and 30 000 lb. The important question, therefore, is this: what is it that causes the knee at a unit stress of about 5 000 lb.? The question seems to have been answered in a paper* by Mr. Duff A. Abrams, on "Tests of Bond between Concrete and Steel," in which, besides pull-out tests of embedded rods, Mr. Abrams reports a large number of tests on reinforced beams loaded at the one-third points. He finds (page 207) that: Mr. Eddy.

"* * * bond between concrete and steel may be divided into two principal elements, adhesive resistance and sliding resistance. * * * The adhesive resistance must be overcome before sliding resistance comes into action. In other words, the two elements of bond resistance are not effective at the same time at a given point". (Page 208.) "If we conclude that adhesive resistance was overcome at the first measurable slip, it will be seen that the adhesive resistance was about 60% of the maximum bond resistance. This ratio did not vary much for a wide range of mixes, ages, size of bar, condition of storage, etc. * * * Sliding resistance reached its maximum value for plain bars of ordinary mill surface at a slip of about 0.01 in. The constancy in the amount of slip corresponding to the maximum bond resistance for a wide range of mixes, ages, size of bar, conditions of storages, etc., is a noteworthy feature of the tests. With further slip the sliding resistance decreased slowly at first, then more rapidly, until with a slip of 0.1 in. the bond resistance was about one-half its maximum value." (Page 216.) "Slip of bar was a phenomenon in all beam tests in which careful slip observations were made. * * * Slip was first observed in the middle region of the span at loads producing a tensile stress in the steel of about 6 000 lb. per sq. in. * * * As the load was increased, slip of bar progressed through the outer thirds toward the ends of the beam at a rate nearly proportional to the increase of load."

Without making further quotations from this important paper, it is clear that any initial shrinkage stresses which the concrete may exert on the steel are limited in their action by the bond, so that they have no important effect on the steel after it reaches a unit stress of 6 000 lb., and therefore they need not be considered as having any influence on working stresses after that. The knee of the graph of the steel stresses in beams is evidently reached when the adhesion ends and the slip begins in the central region, which later progresses into the end thirds, this masking any initial shrinkage effect.

In the tests of these simple beams (page 218) "the maximum bond resistance was materially increased by the additional overhang" at the ends of the beams beyond the supports. In continuous beams it

* *Bulletin No. 71*, Engineering Experiment Station, University of Illinois, 1913.

Mr. Eddy.

is evident that there is no opportunity for the rods to slip at the points of inflection, as they may at the ends of simple beams, and for that reason such beams may be taken as having a very long overhang. Slip in the central portion of a simple beam makes it act more and more like a bowstring girder as the slip progresses toward the ends, while a continuous beam has this tendency checked at the points of inflection. The same thing occurs in a flat slab. The graphs of the reinforcing rods given in the various tests of flat slabs supported on columns exhibit the same phenomenon of a knee as do simple beams, but usually at a much lower unit stress than 6 000 lb.

Apparently, the sharp change of direction of the graph at the so-called knee is a complex result dependent both on shrinkage and slip, which are related to each other in flat slabs somewhat otherwise than in beams, for this reason, if for no other, that such slabs have a depth not much more than half as great as beams of equal span, and the shrinkage grip of the concrete acts somewhat differently on crossed rods than on parallel rods. These, in some way, apparently, bring it about that the shrinkage stresses in the steel in flat slabs disappear at much lower steel stresses than in beams, and the slip is restricted to a small area at and around the column caps, so that the deflections due to this cause in the case of beams is very greatly reduced in the case of flat slabs.

The fact that the graph in beams is practically straight within the range of the working and test unit stresses from 16 000 to 30 000 lb., and that the neutral axis usually varies by much less than 10% of the depth on either side of the mid-depth, and, further, that the center of compression remains practically fixed in the beam for considerable variations of n, the ratio of the steel and concrete moduli, seem to destroy the cogency of Mr. Jonson's objections to the treatment of reinforced concrete on the basis of a suitably modified elastic theory.

It is slabs, however, rather than beams, which should claim our principal attention in this discussion. It appears that the most significant phenomenon exhibited by a panel supported at its edges by walls, or relatively stiff beams, is one which has been overlooked in the discussion thus far, a phenomenon which is exhibited by both slabs and plates in common. The experiments of Bach on plates supported in this manner showed that the failure of such plates was caused by their cracking along valley lines starting from each corner of the panel and almost exactly bisecting the corner angles, regardless of the square or oblong dimensions of the panel.

It is not difficult to imagine how this would occur, for, assume the plate to be supported, to begin with, on corner posts only, and after it has been deflected and has bent downward under the loading,

that it be gradually lifted by screw-jacks which raise stiff beams under the edges of the panel. In this way it is evident, at any time when the deflection of a side has been partly removed, that there is a sudden change of curvature which approaches discontinuity between the part of the slab that has been lifted on the beam and that part not yet lifted. Such a valley line, by reason of the comparatively sharp curvature across it, would be a line of great stress. Now, the analysis which has been proposed does not deal with this phenomenon at all, although it is the one thing of primary importance. The writer has attempted to treat this matter in the book previously referred to, and he knows of no other attempt at a theory of it. The attempted theory is shown to be in good accord with all available tests. Any theory which ignores, as does the present theory, this the most noteworthy experimental phenomenon of a thin slab with relatively stiff supports at the edges of the panels, cannot command our confidence, at least until it can be shown that it is in accord with experimental results such as seem to be totally lacking in this development. Mr. Eddy.

3.—Ratio of Lateral Distortion in Deformed Slabs and Plates.—The ratio of lateral distortion designated by K or by $\frac{1}{m}$ in the foregoing theory, which has been called Poisson's ratio, is in fact something very different from what is ordinarily designated by that phrase, and should no longer be called by that name. Poisson's ratio is the relative amount of the lateral compared with the longitudinal distortion, when a piece of material such as a flat plate or rod is elongated or shortened by direct stress. What occurs in the steel when a reinforced slab is subjected to bending is something quite different from the stretching of a flat plate, and is much more nearly analogous to the bending of a plate which has been stamped with a die into a pattern with alternate hills and valleys or dome-shaped convexities and saucer-shaped concavities, since that is the shape of the enclosed steel mat inside of a flat slab, a mat which, by reason of its embedment of interlocking concrete and its high comparative rigidity, acts not like a flat plate, but instead like a deformed continuous sheet of steel composed of many elevations and depressions. In order to form a correct idea of the deformation of such a sheet on bending, imagine a single saucer-shaped concave plate to be somewhat bent about a diametral line. One diameter of the saucer becomes less while that at right angles becomes greater. The radius of curvature of the normal section containing the smaller diameter thus becomes smaller while the radius of the other section becomes greater. The necessary connection and relation of these changes of curvature and the accompanying compressions and elonga-

Mr. Eddy.

tions on the surfaces of the plate have nothing whatever to do with the molecular phenomenon which controls Poisson's ratio, but are due to the geometry of curved surfaces, although they might be modified somewhat by the magnitude of Poisson's ratio for the particular materials of which the curved plate is composed.

It is evident that, for a plate forming a segment taken from a hollow sphere of incompressible material, the distortion due to bending it would be such as to make the lateral and longitudinal distortions approximately equal. Thus K would be nearly equal to unity for such a substance, no matter how small Poisson's ratio might be; but, in such a plate, formed of some compressible material, K would be smaller. Its actual value would be a matter of experiment. It is this ratio of distortion of deformed plates that is contained in Equations (1), and not Poisson's ratio proper. The latter plays a very subordinate rôle in this theory, and the actual value of this ratio for the kind of material used has little or no relation to the value of K that must be used in these equations. It may be noted further that, in addition to the curvatures of the steel in the slab, the slab itself is likely, under its own weight and as an after effect of loading, to have some small deformations of a kind similar to those due to the curvatures of the steel mat.

The steel mat, in a flat slab on columns, however, does not consist entirely of convex and concave areas, for between these lie areas of twisted curvature which occupy approximately half of the total area of the slab. The mean value of K in Equations (1) depends in almost equal degree on these areas of saddle-shaped curvature and on those that are convex or concave. So far as the concurrent evidence of tests goes, the mean value of K for flat slabs supported on columns with the ordinary arrangement of steel is $K = 0.5$, although the value of Poisson's ratio for concrete alone certainly is not half as large as that. The manner in which K affects the deflections and resisting stresses of the steel is by the reduction factor, $(1 - K^2)$, and its influence, consequently, is much less than is often tacitly assumed by those who reason about it, as may be seen from the following tabulation:

$$K = 0.1 \quad 0.2 \quad 0.3 \quad 0.4 \quad 0.5$$
$$1 - K^2 = 0.99, \ 0.96, \ 0.91, \ 0.94, \ 0.75$$

from which it appears that, for values of K less than 0.2, its effect may be disregarded, but for $K = 0.5$, the effect modifies the values obtained by disregarding K by 25% at most.

So far as is known, this is the first time that it has been pointed out that the value, K, which must be used in equations of flat plates, is to be determined principally by considerations other than the molecular properties of the particular materials of which the plate is

composed, a fact which obviates the many criticisms which have been passed on any theory using any value larger than that found for the material of the plate. Those criticisms have assumed that, without question, the true value of Poisson's ratio for the materials composing the plate must of necessity be used in Equations (1), which is not the fact. Mr. Eddy.

The tests that have been made of flat slabs on columns have shown that, when the steel runs in belts over the columns, the stresses are almost entirely limited to the panels which carry the loads, and little effect is propagated from panel to panel. This has been thought by some to be due entirely to the stiffness of the supporting columns, as it undoubtedly is in part; but the foregoing discussion reveals an additional reason why the stresses in a panel are self-contained, much as it would be were it an arched or bow-string girder construction running to the columns. Such, however, is not the case to such a marked extent with two-way reinforcement in which rods cross the sides of the panels at mid-span and propagate moments more readily from panel to panel.

In the first of these constructions there are only comparatively small movements of the lines of inflection when a single tier of panels across a floor is subjected to a test load, and the action is not the same as it would be in a wide beam, because the action is more or less like attempting to collapse or flatten out a corrugated pipe instead of a plain pipe. It brings out the resistance of the reinforcement in a different and more effective manner.

It must be remembered that the actual statical moments of given loads in any panel cannot be altered by any process. The only question is how these moments are subdivided and resisted by the reinforcement. Other things being equal, that certainly occurs most economically when each panel is influenced least by adjacent panels, and at the same time each panel assists its surrounding panels as much as possible. In the case of a slab supported on relatively stiff beams or walls, each panel is largely independent of surrounding panels, and the lines of inflection lie relatively near the beams. The relative flexibility of the the slab is so large, and the deflection of the beams which support it is relatively so small, that the effect of their deflection is less important than seems to be imagined by Messrs. Janni and Jonson, and is negligible compared with the other inaccuracies of the method.

L. J. MENSCH,* M. AM. SOC. C. E. (by letter).—The author's assumption for the distribution of loading of the central strips of a rectangular slab is probably not far out of the way; yet his theory is misleading, because it is as little proper to assume that the average Mr. Mensch.

* Chicago, Ill.

Mr. Mensch.

bending moment for such a slab should be figured as the moment of the central strips as it would be to assume that the eye-bar of a pin-connected bridge is strained only for a width equal to the diameter of the pin. During the last 12 years many investigators have divided rectangular slabs into a number of strips, thereby obtaining a clearer view of the behavior of the slabs. Danusso went further,* and investigated the influence of the diagonal strips which connect the center of the supporting girders and others parallel to them and nearer to the corners, and found that they greatly relieve the central strips. According to his theory, the average bending moment for a square slab freely supported on four sides is about $\frac{w\,l^2}{30}$, and, for one fixed on four sides, the average bending moment is about $\frac{w\,l^2}{70}$ in the center of the span and $\frac{w\,l^2}{34}$ at the supports. This seems to agree with nearly all recorded tests on such slabs.

Very instructive tests were made on two slabs of the "Palais de Costume" at the Paris World's Fair in 1902. One slab was about 22 ft. square, 6 in. thick, reinforced by $\frac{5}{8}$-in. round bars about $6\frac{1}{2}$ in. from center to center, and supported by light girders on very light columns. At a total load of about 500 lb. per sq. ft. the girders and columns were at the point of failure, and the girders had to be supported by temporary props and the test discontinued. The slab itself did not show any sign of very near failure, indicating that the negative bending moments produced great torsional stresses in the narrow girders and dangerous eccentric loadings in the light columns at a stage of loading which was probably only two-thirds of the ultimate carrying capacity of the slab. Better results were obtained with another slab, about 21 by 24.5 ft., supported on girders 18 in. wide and 24 in. deep, which girders were of considerably greater span than the slab proper. In this case, also, the girders failed first, which happened at a loading corresponding to an average bending moment in the slab of $\frac{w\,l^2}{38}$. The slab itself did not show any very near approach to failure.

We can cite also the very thorough tests made by Professor Bach, in 1914, on square and rectangular slabs simply supported on four sides. For comparison, Professor Bach tested also beams simply supported on both ends, having the same depth and the same percentage of reinforcement as the slabs. The diagonal strips (although the reinforcement ran only in two directions) were carrying a great part of the load on the slab, as was shown by the direction of the

* *Il Cemento*, 1912.

Mr. Mensch.

cracks on the underside of the slab, and the average moment at the ultimate load was found to be about $\frac{w\,l^2}{28}$. The tests on rectangular slabs, with side ratios of 1:1½ and 1:2, and with the same percentage of reinforcement in both directions, gave the remarkable result that the ultimate load per square foot was from 77 to 85% of that obtained for a square slab the length of the sides of which was equal to the smaller side of the rectangular slabs. This can only be explained by the very pronounced action of the diagonal strips and by the fact that the limit of elasticity is first reached in the short direction, producing comparatively large deflections, thus allowing the longer span to take up the remainder of the load.

The writer heartily agrees with Mr. Jonson that the theory of reinforced concrete, as found in nearly all textbooks, ordinances, and in the reports of the Joint Committee, is rather crude, and should be entirely discarded. The theory is wrong because the plane-section theory and Hooke's law do not apply to reinforced concrete, even at ordinary loads—a fact proved by Professor Schule 14 years ago—and, as may be expected, is far from the truth at ultimate loads. Because we encounter very great difficulties in investigating the properties of any material near rupture, making it practically impossible to measure the flow or plasticity of the materials, the great mathematicians of about 100 years ago developed theories for the strength of materials based on stresses below the elastic limit, which, although they were a great improvement over the guess methods previously used, do not lead to constructions having the same factor of safety in every part. Following faithfully their lead, we were taught to allow stresses of about one-fourth of the ultimate strength of the materials, and have trusted ever since to good luck that our structures, designed according to these rules, have a factor of safety of about 4.

During the last 30 years a great number of testing laboratories have been erected in various parts of the world, and we now have more information about the strength of structures than ever before. Very slowly the fact has been brought out that our theories do not explain the ultimate strength of many members of constructions, and that it is advisable to use different working stresses for such members. This Society has recently helped to make most thorough tests on structural steel columns. No theory, according to the old standards, seems to fit these tests, but, if we take into consideration the properties of steel at the time of failure, especially the fact that the modulus of elasticity near rupture is considerably less than the initial value of 29 000 000 lb. per sq. in., on account of the flow of the material, and if we introduce the correct value of E in Euler's

Mr. Mensch.

formula, we readily obtain a good agreement between theory and test. Of course, where $\frac{l}{r}$ is large, the ultimate unit stress is below the elastic limit, and in this case E equals 29 000 000, and for such long columns Euler's formula always gave satisfactory results. Similar discrepancies in old established theories were lately found also for rolled I-sections in bending, and there is no doubt that tees, angles, and other unsymmetrical sections will show still greater variations. If such is the case with a homogeneous material like steel, we may question in a still greater degree all reinforced concrete theories which are based on Hooke's law and the plane-section theory.

The writer has shown* that neither the plane-section theory nor Hooke's law is required to explain the results of tests on reinforced concrete girder and slab construction which failed without bond or diagonal tension failure.

Fig. 4 represents the ideal stress distribution in a section of a beam at the time of failure. Let f_c = the ultimate strength of concrete, in pounds per square inch, as shown in cylinder tests. Let f_s = the ultimate strength of reinforcing steel in reinforced concrete construction, which experience shows is about a mean between the elastic limit and ultimate strength, and all other notations as given by the Joint Committee; then, from the necessary condition that total compression equals tension, we have

$$\frac{2}{3}\, b\, k\, d\, f_c = p\, b\, d\, f_s$$

$$k = 1.5\, \frac{f_s}{f_c}\, p$$

$$M = p\, b\, d\, f_s \left(d - \frac{3}{8}\, k\, d\right) = p\, b\, d^2\, f_s \left(1 - \frac{3}{8}\, k\right)$$

or $$\frac{M}{b\, d^2} = p\, f_s \left(1 - \frac{3}{8}\, k\right)$$

or $$M = A_s\, f_s\, j\, d, \text{ when } j = \left(1 - \frac{3}{8}\, k\right).$$

The writer has shown (in the paper mentioned) that by assuming f_s = 45 000 lb. per sq. in. for mild steel, 72 000 lb. for high-carbon steel, and 110 000 lb. for commercial high-carbon drawn-steel wire, the ultimate moments, according to this formula, agree, within a small percentage, with the ultimate moments of nearly all published scientific tests on beams which he could find. Hence, the value of n is of no account in the investigation of the strength of a beam. In regard to its probable value at the ultimate load, it is known that the steel reinforcement in nearly all tests first shows signs of failure

* *Journal*, Am. Concrete Institute, December, 1914.

Mr. Mensch.

before the concrete is highly strained in compression, which means that the steel reaches and exceeds the elastic limit long before the concrete attains it in compression; when the steel exceeds the elastic limit, E drops very suddenly, and its probable value, just before rupture of a reinforced concrete beam, is less than 1 000 000 lb. per sq. in. The concrete in compression is not as plastic as steel, and it is probable that its modulus of elasticity near rupture is not less than from 300 000 to 500 000 lb. per sq. in., or the probable value of n at the ultimate load $= \frac{1\,000\,000}{500\,000} = 2$, and not—as Mr. Jonson states—30 or 40. Mr. Jonson's statement that "all calculations of reinforced concrete made on the assumption that the ratio, n or E divided by E_c, is a constant are unreliable * * *" shows that he is not familiar with the literature on reinforced concrete or statically indeterminate structures. Except for the influence of temperature

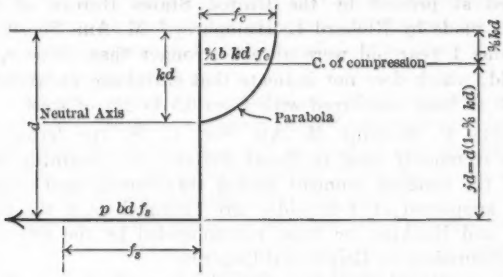

FIG. 4.

variation and shrinkage, the stresses in statically indeterminate structures never depend on the absolute values of $E\ I$, but on a function of the ratio of the value of $E\ I$ at any particular point, x, to a fixed value of $E\ I$ at any important point. Where $E\ I$ is constant, the moment of inertia has no influence whatsoever on the stresses caused by the indeterminate values, and, where I varies, the stresses depend generally on a function of the ratio of $\frac{d^3}{d_x^3}$ for rectangular sections. Assuming even that the moment of inertia is not proportionate to the 3d power of the depths of the section, the mistake appears only in a function of the ratio, and is of small influence; a mistake of 100% in the moment of inertia causes often a change in the stresses of only a few per cent.

Professor Morsch investigated this subject about 8 years ago and found a very fair agreement between theory and practice. More scientific tests were made by Professor Scheit and Mr. E. Probst on

Mr. Mensch. continuous girders on three to five supports. It is well known that, in a girder of constant moment of inertia, on three equidistant supports, the statically unknown moment over the central support is $\frac{Wl}{8}$. Their tests showed that the girder failed at the moment over the central support of $\frac{Wl}{10}$. The actual bending moment is smaller than that given by the elastic theory, which is easily explained by the fact that the elastic limit over the supports is reached long before the center of the spans is strained to the elastic limit, which has an effect of equalizing the moments over the supports and in the center of the span. These investigators obtained similar results for girders on four and five supports and for framed structures.

The influence of shrinkage of concrete on the strength of reinforced concrete beams is not solved yet, but is being thoroughly investigated at present by the United States Bureau of Standards. The tests made by Richard L. Humphrey,* M. Am. Soc. C. E., show that beams 1 year old were always stronger than those 4, 13, or 26 weeks old; which does not indicate that shrinkage unfavorably affects beams 13 ft. long reinforced with from 0.5 to 2% of steel.

Mr. Marsh. CHARLES F. MARSH,† M. AM. SOC. C. E. (by letter).—The coefficients commonly used in Great Britain, for obtaining the proportions of the bending moment acting transversely and longitudinally in slabs supported on four sides, are obtained from the formulas of Grashof and Rankine, or those recommended by the French Government Commission on Reinforced Concrete.

An inspection of the values given by these formulas will show that in both cases the transverse coefficient approaches unity as the ratio, $\frac{l_1}{l}$, increases, but never reaches this value; and the longitudinal coefficient approaches but never reaches zero as the ratio, $\frac{l_1}{l}$, increases, and, from the nature of the case, these would appear rational and obvious results.

By the use of Mr. Janni's formulas, the transverse coefficient is unity and the longitudinal coefficient is zero when $\frac{l_1}{l} = \frac{5}{3}$, and their use for ratios of $\frac{l_1}{l}$ greater than $\frac{5}{3}$ gives a transverse coefficient greater than unity and a minus quantity for the longitudinal coefficient. Such results do not impress one as being in accordance with the facts.

* *Technologic Paper No. 2*, Bureau of Standards.

† London, England.

Mr. Janni obtains his formulas by considering the slab as divided into systems of beams parallel to the short and long sides of the slab and equating their deflections at the center; the formulas of Grashof and Rankine are obtained by the same method. Mr. Marsh.

The introduction of the effect of Poisson's coefficient is doubtless essential, from an academic point of view, but the practical utility and accuracy of the results are of doubtful value, especially when, as a preliminary, the important assumption is made that the moment at P is reduced to two-thirds of its theoretic value by reason of the doubtfulness as to the efficiency of the fixation.

With respect to Mr. Jonson's discussion, it might be well to point out that the generally accepted methods of treatment, working stresses, and coefficients were recommended by the various authorities after full consideration and knowledge of the general effect of the various influences other than those actually provided for in the formulas, and there appears to be no reason to doubt that structures designed by the use of such formulas and the stresses and coefficients recommended will, if properly constructed, be amply sufficient to serve the purposes for which they are designed.

The initial strains due to the shrinkage of the concrete when setting do without doubt have an effect on the structure, but other conditions also affect the resistance, such as loading and unloading, temperature and humidity, the greater facility of the reinforcements than of the concrete in recovering after straining, etc.

In any case, it is very doubtful whether Mr. Jonson's conclusions with respect to the effect of the initial strains due to shrinkage are correct, and it is more than probable that these strains would add to the resistance of a reinforced concrete member.

Shrinkage of the concrete induces compressive stress in the reinforcements and tensile stress in the concrete and, in the case of a member subjected to flexure, if the concrete does not crack on the compression side of the neutral axis, the resistance of the member is increased; but if the concrete cracks, as the initial stresses are induced before the cracking occurs and the crack must close up before the concrete can be stressed by the loading, the initial strain of the reinforcement must be removed, leaving matters as they were before the shrinkage.

In the case of a member under direct compression, the initial compressive stress on the steel added to the compressive stress due to loading will never approach the permissible working stress on the steel.

From the results of published experiments it would appear that the value of Em for 1:2:4 concrete is not likely to have a range greater than from $-$ 3 000 when the setting takes place in water to $+$ 6 000 when the setting takes place in air.

Mr. Marsh.

With respect to the value of the coefficient, n, it is well known and recognized that its value may vary between wide limits, and that the value used in calculations must necessarily be in a great measure hypothetical.

Many experiments have been made with the object of ascertaining a proper value for this coefficient, and the results have varied considerably, which is hardly surprising, considering the nature of the material under test.

Mr. Jonson concludes, from certain recently conducted experiments, that the modulus of elasticity of concrete decreases with age, whereas similar experiments in the past have indicated an increase. From a careful study of experiments bearing on the value of this modulus conducted up to about 1908, it was concluded that a fair average value was about 1 740 000 under a stress of 600 lb. per sq. in., giving n a value of about $17\frac{1}{2}$, but that the tendency of the concrete to take a permanent set, while the steel was truly elastic, would have an effect equivalent to a decrease in the value of n, and, consequently, it was concluded that the adoption of a value of 15 for n was a reasonable assumption. It was also found that the results of actual experiments on reinforced concrete beams justified this value.

The treatment of continuous construction as consisting of a series of cantilevers supporting beams at their ends is a method which is frequently adopted, but its accuracy is questionable, especially where the loading may vary and the spans are unequal.

For the ordinary floor design, it would appear that approximate coefficients for the bending moments, such as those given in the London County Council Regulations, might be used with perfect safety and with a great simplification of the calculations.

Mr. McMillan.

FRANKLIN R. MCMILLAN,* ESQ. (by letter).—In the following remarks attention will be given to the questions raised by Mr. Ernst F. Jonson, in his discussion, rather than to the method of calculation proposed by the author; for these questions, which concern the fundamental calculations of reinforced concrete beams, must be settled before we are justified in passing to the refined methods suggested by Mr. Janni.

During the past 3 years, the writer has been conducting, at the Experimental Engineering Laboratory of the University of Minnesota, a series of investigations concerning some of the physical properties of concrete which Mr. Jonson has mentioned as affecting the theory of flexure of reinforced concrete. Although these investigations are still far from complete, considerable data have been accumulated which relate to the questions at issue.

As the value of such calculations as made by Mr. Jonson depends on the correctness of the assumptions, it will be well to present a sum-

* Asst. Professor, Structural Eng., Univ. of Minnesota, Minneapolis, Minn.

Mr. McMillan.

mary of the more important facts and conclusions from these investigations before taking up the discussion.

These results relate principally to the shrinkage and the non-elastic deformation or time yield in reinforced concrete beams, slabs, and columns.* The curves of Figs. 5, 6, and 7 show the results of shrinkage measurements on a number of specimens designed to bring out the effect of several variables. In regard to Fig. 5 little need be said in explanation, as the legends show quite clearly the variations. These results were obtained from 4 by 5 by 24-in. specimens, cast under conditions as nearly identical as possible, and cured side by side, 2 weeks under wet burlap and then open to the ordinary air of the laboratory. Initial readings were taken when the beams were one or two days old, hence the values given represent practically the entire shrinkage. From these curves it will be seen that the total shrinkage is from 0.055 to 0.065%, and that little difference results from varying the proportions, quantities of water, or density, within the limits of ordinary practice. It will also be observed that in nearly every case the shrinkage amounts to 0.05% within the first 60 days.

On Fig. 6 are shown the results of shrinkage measurements extending over periods of from 2 to 3 years, in which somewhat higher values are found than in the specimens of Fig. 5. It will be noted that there is a large difference in the total shrinkage shown by the two slabs in the upper diagram, and that the greater value is shown for the slab on which observations were not commenced until it was 68 days old. As this slab had been covered with wet sand until within 3 days of the zero measurements, there may have been some swelling, which, if subtracted from the values shown, would give the shrinkage from the original state. In some other tests, not included here, a swelling of nearly 0.02% has been observed in 80 days under wet burlap. The concrete of the 6 by 8-ft. slab is considerably more porous than that of the 10 by 10-ft., which may in a measure account for the higher shrinkage, as well as for the quicker response to the change in the humidity of the air, as seen from the undulations of the shrinkage curves. It should be noted that the periods shown on this or any of the other figures do not represent coincident calendar periods for the different specimens; they were plotted to the same set of co-ordinates for simplicity. When plotted on a true calendar scale it is found that the undulations are coincident, showing the seasonal changes in the humidity.

In the lower diagram of Fig. 6 rather high values of total shrinkage are shown; the effect of early wetting on the total shrinkage can also

* For a more extended discussion of these tests, see *Bulletin No. 3, Engineering Series*, University of Minnesota, "Shrinkage and Time Effects in Reinforced Concrete". Also the paper, "Time Tests of Concrete," by F. R. McMillan, *Journal*, Engineers' Club of St. Louis, Vol. 1, No. 4.

Mr. McMillan.

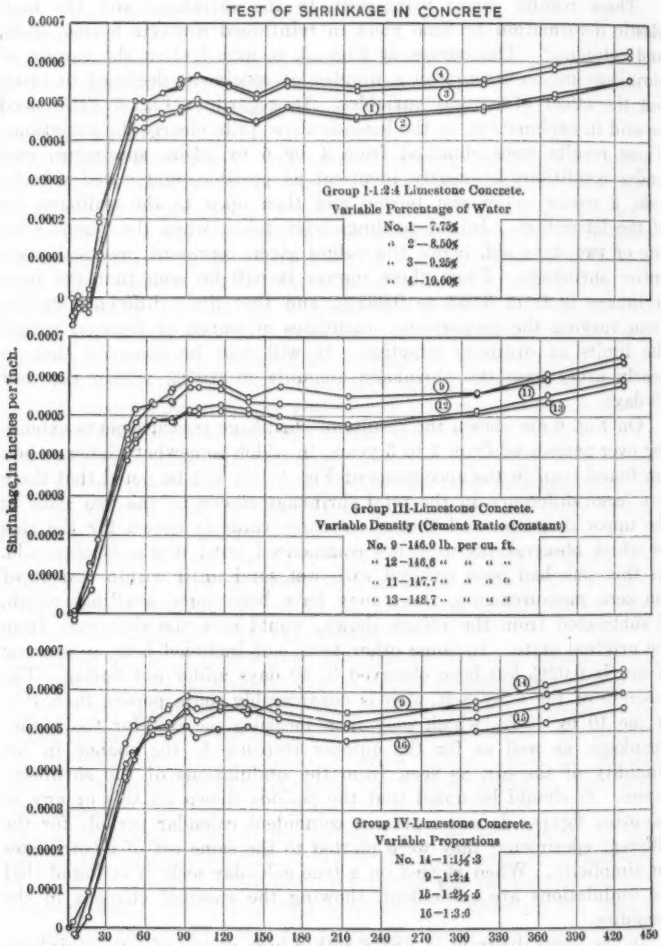

FIG. 5.

be seen. These two beams were identical, except for the methods of curing, as noted on the diagram. That the effect of the early wetting on Beam *B*—or the subsequent immersion—is only to retard the shrinkage, and does not affect the final total amount, can be seen from these curves. This is also indicated by the results from the

Mr. McMillan.

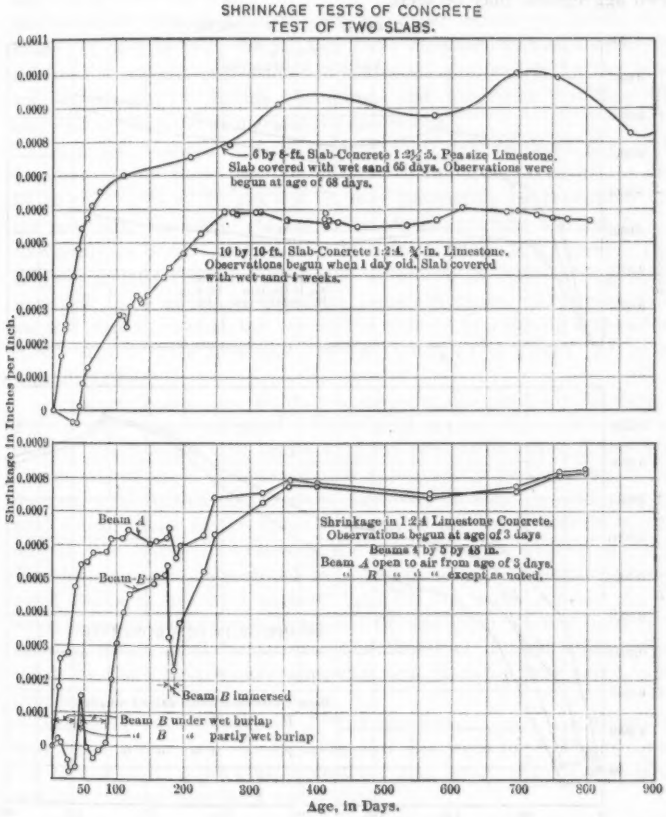

FIG. 6.

6 by 8-ft. slab previously referred to, which show a total shrinkage of nearly 0.1 of 1% beginning after curing 57 days under moist sand.

In the upper curves of Fig. 7 are given the results of measurements on 4 by 5 by 24-in. beams, made from 1:2:4 concrete of three different aggregates, and cured under conditions as nearly identical as possible.

Mr. McMillan.

These results are presented as further evidence of what total shrinkage may be expected, rather than for the comparison of the different aggregates, for with these few tests definite conclusions cannot be drawn. In the lower curves the effect of early wetting on both the limestone and sandstone concrete, as well as the comparison of the two aggregates, may be seen.

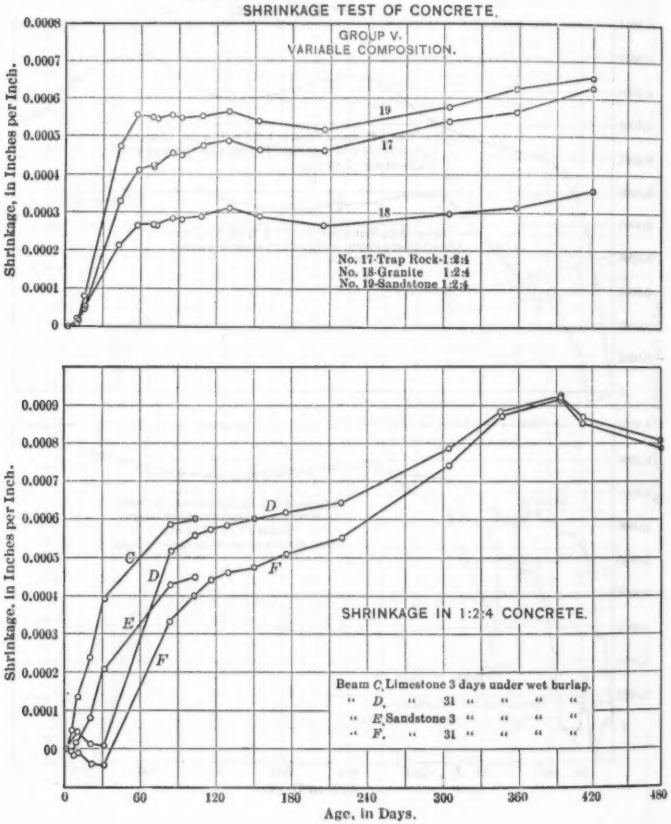

FIG. 7.

That other variables than those controlled in the several series of these tests affect the amount of shrinkage is evident from the varying amounts shown by specimens of nominally the same mixture; for example, the 1:2:4 limestone concrete, shows the following values

for the different tests: in Fig. 5, from 0.055 to 0.065%; in Fig. 6, from 0.06% for the 10 by 10-ft. slab to 0.08% for Beams *A* and *B*; and, in Fig. 7, 0.09% for Beam *D*. This is further illustrated by the values of 0.065 and 0.092% shown by the upper and lower curves for the 1:2:4 sandstone concrete of Fig. 7. These differences are considerably greater than found for those tests shown on Fig. 5 in which the variables were regulated. Among other causes to which these differences may be due, the following are suggested as probably having considerable weight: variations in materials assumed to be the same, and differences in mixing, tamping, and otherwise handling the materials at the time of making the specimens. Mr. McMillan.

From the foregoing it is evident that definite laws cannot be formulated from these tests; however, two important conclusions may be drawn: First, as to amount, it may reasonably be concluded that the minimum shrinkage to be expected in concrete allowed to dry thoroughly is 0.05%, and that values from 20 to 50% greater than this will usually result; second, the difference in early curing conditions has little effect on the final total shrinkage. Concrete cured wet will swell somewhat, but, when it is exposed to a drying atmosphere, it will shrink fully as rapidly and as much as if placed in the air when first cast.

In regard to the time yield or non-elastic deformation, the data on Figs. 8 and 9 are presented. On Fig. 8 appear the results of tests on four small beams kept under load for periods of 200 and 500 days. The details of these tests are shown quite clearly by the notes on the diagrams; in further explanation, however, it may be said that the total deformations at the upper surfaces of the beams were measured over an 8-in. gauge line crossing the point of application of the load. The shrinkage was determined from measurements on identical beams cured similarly but held without load for the same period. As the stress increases rather rapidly toward the center, in such a short span, the total measured deformations—and therefore the net deformations shown by these curves—are somewhat less than the true value, probably from 5 to 10 per cent.

Beams 11 and 13 were of 1:2:4 concrete, of pea size limestone, kept wet for one day. Beams 118 and 121 were of 1:2:4 concrete, the former with ¼ to ¾-in. limestone, the latter with Kettle River sandstone; these were kept wet 3 days.

An inspection of the curves of Fig. 8 shows that the moduli of total deformation reduce considerably in the periods for which these measurements were made. Table 2 gives the ratio of the deformation shown by these curves at several different ages to the initial deformation.

In Table 2 the remarkable regularity in the values for the three limestone beams, 11, 13, and 118, should be noted. Although the

Mr. McMillan.

initial moduli may differ, the rate of the progressive movement is about the same. No determination of the elastic modulus was made on the concrete of these beams at the time of loading, but calculation from the bending moment indicates values ranging from 1 600 000 to 2 200 000 for the limestone, and 3 000 000 for the sandstone. In these calculations the conditions of a homogeneous beam, 4 by 5 in. in cross-section, were assumed, as it is known that no cracks developed at first loading. On the basis of these values, we may expect at 200 days a value of n from 26 for the sandstone to 50 for the limestone, and from 50 to 60 for the limestone at 500 days.

TABLE 2.

Beam.	Initial deformation, in inches per inch.	Ratio of Net Deformation to Initial Deformation.			
		30 days.	90 days.	200 days.	530 days.
11	0.000385	2.49	2.66	3.50	4.09
13	0.000302	2.48	2.78	3.28	3.74
118	0.000246	2.40	2.84	3.29	....
121	0.000180	1.57	2.08	2.68	....

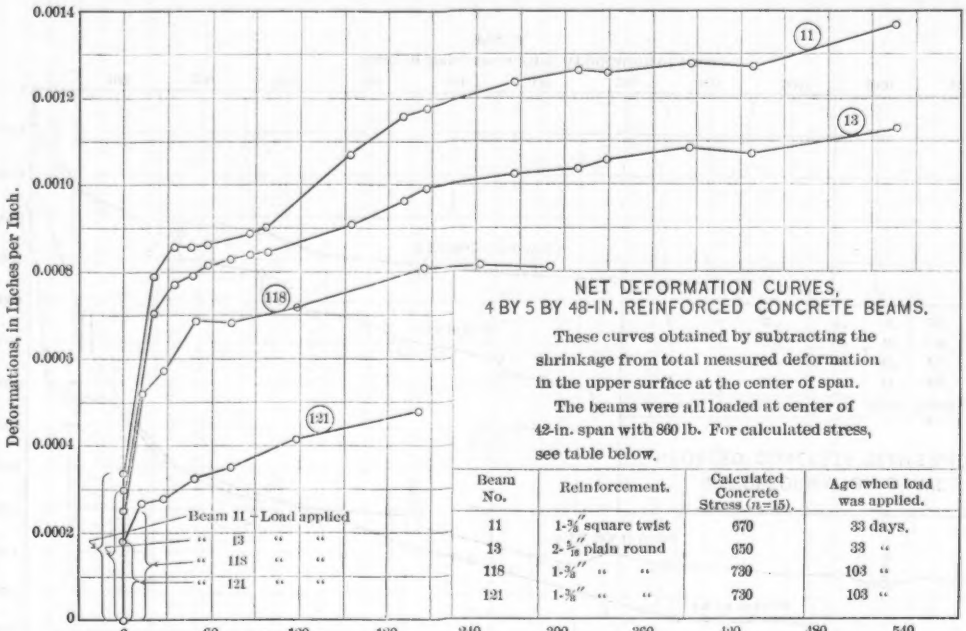
By net deformation is meant total deformation minus the shrinkage. It includes the deformation due to load and time yield.

TABLE 3.

Specimen.	Coarse aggregate.	Nominal proportions.	Time kept wet.	Age at Application of the Various Loads.	
				Dead load.	Other loads.
Beam *A*....	Limestone, pea size.	1 : 2 : 4	1 day	.....	Dead load and 860 lb. at center applied at age of 33 days.
Beam *B*. ..	Limestone, ¼ to ¾ in.	1 : 2 : 4	(not wet)	41 days	Loaded at one-third points. Total of 500 lb. at 80 days. After several changes, on and off, total of 1 500 lb. at 88 days
Slab *C*.....	Limestone, ¼ to ¾ in.	1 : 2 : 4	31 days	135 days	Live load 50 lb. per sq. ft. at 309 days. Increased to 100 lb. at 410 days.
Slab *D*.....	Limestone, pea size.	1 : 2½ : 4	57 days	59 days	Live load 50 lb. per sq. ft. at 68 days. Increased to 100 lb at 71 days. Live load removed at 82 days, and re-applied at 94 days.

On Fig. 9 are shown the net deformation curves for two more beams and two slabs. These curves differ from those of Fig. 8 in that the load was not applied at one time. For example, in the curve for the 10 by 10-ft. slab the deformation shown at the first day was due to

Mr. McMillan.



NET DEFORMATION CURVES,
4 BY 5 BY 48-IN. REINFORCED CONCRETE BEAMS.

These curves obtained by subtracting the shrinkage from total measured deformation in the upper surface at the center of span.

The beams were all loaded at center of 42-in. span with 860 lb. For calculated stress, see table below.

Beam No.	Reinforcement.	Calculated Concrete Stress (n=15).	Age when load was applied.
11	1-$\frac{3}{8}$″ square twist	670	33 days.
13	2-$\frac{5}{16}$″ plain round	650	33 "
118	1-$\frac{3}{4}$″ " "	730	103 "
121	1-$\frac{3}{8}$″ " "	730	103 "

FIG. 8.

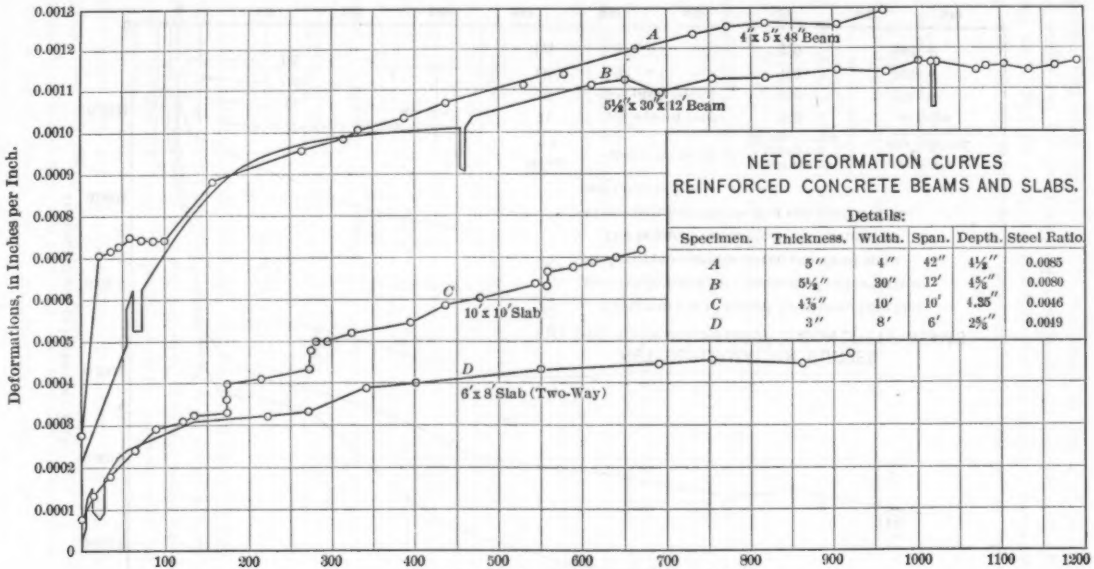


FIG. 9.

Mr. McMillan.

Mr. McMillan.

the dead load only (55 lb. per sq. ft.), and no further load was applied until the 174th day, when a live load of 50 lb. per sq. ft. was added, with a similar increase 100 days later. The increase in deformation at 560 days was the result of an overload applied for the purpose of breaking the concrete in tension, which, up to this time had shown no signs of cracking. Table 3 gives the mixture, age, and loading of these beams and slabs, and Table 4 the ratios, at different ages, of net deformation to load deformation. In the calculation of these ratios, the net deformation at the given age, as shown by the curve on Fig. 9, is divided by the sum of the load deformations for all previous load increments. Thus, for the 250th day on the 10 by 10-ft. slab, the ratio is 3.2, obtained by dividing 0.000428, the net deformation from the curve, by (0.000076 + 0.000058), the dead-load deformation plus the live-load deformation on the 174th day.

TABLE 4.

Specimen.	Load Deformations.					Ratio: Net Deformation to Load Deformation at:				
	Dead load.	Live load.	Time, in days.	Live load.	Time, in days.	50 days.	100 days.	200 days.	650 days.	950 days.
Beam *A*....	.....	0.000280	0	.....	...	2.57	2.68	3.39	4.25	4.60
Beam *B*....	0.000200	0.000035	46	0.000075	54	....	2.32	3.11	3.63	3.71
Slab *C*.....	0.000076	0.000058	174	0.000043	275	2.90	....	3.20	4.00	....
Slab *D*....	.....	0.000042	0	0.000065	3	2.24	2.66	3.08	4.11	4.39

Time refers to interval from first application of load.

In the ratios of net to load deformation in Table 4, practically the same values are found as for the corresponding periods in Table 2. The initial moduli for three of these specimens were determined, with the following results:

Beam *B*..... 3 460 000 at 27 days.
Slab *C*..... 3 300 000 at 135 days.
Slab *D*..... 2 500 000 at 72 days.

These give values of n ranging from 9 to 12 at the time of application of the loads, from 20 to 30 at 3 months, and from 33 to 53 after 2 years.

The conclusions to be drawn from these tests of shrinkage and time yield, which apply to the question raised by Mr. Jonson, may be summed up as follows: First, in concrete allowed to dry thoroughly a shrinkage of from 0.06 to 0.07% may ordinarily be expected, with a minimum value of 0.05%; second, the modulus of total deformation will be from one-half to one-third of the initial modulus in a few months, and about one-fourth or less after 2 years; that is, on the

Mr. McMillan.

usual basis of an initial value of n ranging from 9 to 15, values from 20 to 30 may be expected in a few months and from 35 to 60 at 2 years.

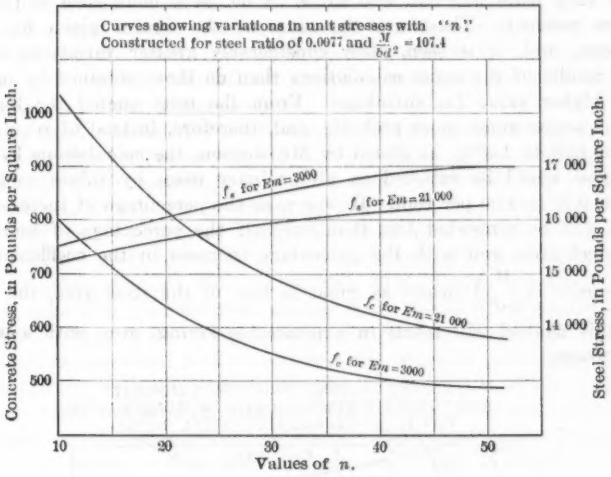
Now, to apply the values just quoted for shrinkage and time yield to the calculation of beams in the manner followed by Mr. Jonson, the upper diagram of Fig. 10 has been prepared. The formulas of Mr. Jonson from which this diagram was constructed assume the condition that the beam is not free to shrink, and therefore the concrete cracks, a condition that may be possible, though probably not the usual one.

The diagram referred to assumes a beam with a steel ratio of 0.0077 and loaded so that $\frac{M}{b\,d^2} = 107.4$, the value corresponding to unit stresses of 16 000 and 650 for $n = 15$. The true stresses in such a beam for various values of n can be read directly from this diagram. The two sets of curves show the extreme cases of shrinkage, the value, 0.01% ($Em = 3\,000$), being the minimum suggested by Mr. Jonson, and the other, 0.07% ($Em = 21\,000$), being the probable ordinary maximum, as shown by the experiments quoted. From these curves it is seen that, with a shrinkage of 0.07%, a beam designed by the usual assumption would have a concrete stress anywhere from 800 for $n = 20$ to 580 for $n = 50$, and a steel stress of from 15 600 to 16 300, within the same limits. For a shrinkage of 0.05% the values would be a little less for the concrete and but slightly more for the steel.

The quantity of steel to use for any unit stress desired can best be determined from the lower diagram of Fig. 10, which has been prepared for a fixed unit stress and several ratios of steel. To illustrate: With 650 as the desired limiting concrete stress and $n = 40$ assumed to represent the probable condition of total deformation, by interpolation from this diagram it is seen that a steel ratio of 0.0085 would be required, with the resulting value of $\frac{M}{b\,d^2}$ at 117. This is 10% more steel than required for the usual assumptions, and gives 9% greater resisting moment. For $n = 30$, the same concrete stress would require only 0.7% of steel, and would give a value of 100 for $\frac{M}{b\,d^2}$; this is 9% less steel and 7% less moment than for the beam designed on the usual assumptions.

Fig. 11 is similar to the lower diagram of Fig. 10, using the value of 3 000 for Em. From this diagram it is seen that, for a concrete stress of 650, 1.2% of steel would be required for $n = 40$, and 1.03% for $n = 30$. The corresponding values of $\frac{M}{b\,d^2}$ are 153 and 138, respectively. When compared with a beam designed by the usual

Mr. McMillan.



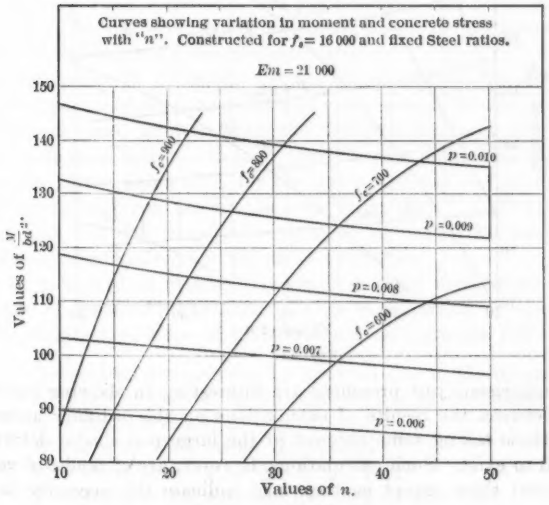


FIG. 10.

Mr. McMillan.

assumptions, the values for $n = 40$ give a beam of 56% more steel and 42% more moment, and for $n = 30$, 34% more steel and 28% more moment. These are the same as the figures given by Mr. Jonson, and, it is seen, show considerably greater variations from the results of the usual calculations than do those obtained by using the higher value for shrinkage. From the tests quoted the higher value seems much more probable, and, therefore, instead of requiring from 1.03 to 1.20%, as stated by Mr. Jonson, the calculations by his method would be satisfied in all ordinary cases by values ranging from 0.75 to 1.00 per cent. However, as the percentage of increase in cost will be somewhat less than one-half the percentage of increase in steel area, and with the percentage increase in the coefficient of resistance $\left(\frac{M}{b\,d^2}\right)$ nearly as great as that of the steel area, the use of this method will result in a noticeable saving, even with a large shrinkage.

CURVES SHOWING VARIATION IN MOMENT AND CONCRETE STRENGTH WITH "n" CONSTRUCTED FOR $f_s = 16\,000$ AND FIXED STEEL RATIOS.

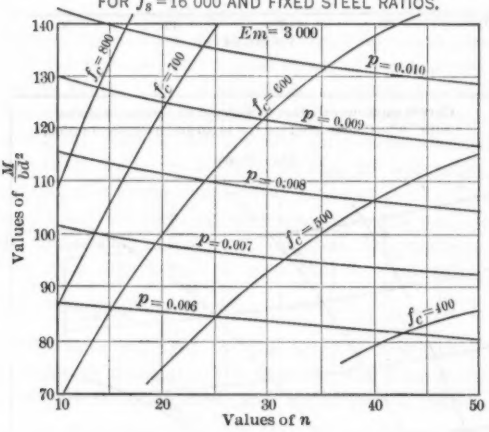

FIG. 11.

The comparisons just presented are interesting in showing possible variation between the results of calculations on the ordinary assumptions and those taking some account of the large non-elastic deformations found to exist. Such calculations, however, are of doubtful value at the present time, except as they may indicate the necessity for a thorough study and revision of the theory of reinforced concrete beams, for they are based on assumptions varying enough from the real con-

Mr. McMillan.

ditions to involve greater errors, perhaps, than those they seem to have pointed out. For example, the assumption that the beam is anchored so that the steel does not change in length from the shrinkage is probably not often realized in practice, and, if so, the concrete will probably crack, if at all, at irregular intervals rather than in the manner assumed in the analysis.

Until further knowledge is obtained of the inter-action of the materials under the various conditions that are likely to be encountered in the completed structure, it does not seem desirable that any change from the present practice in design be attempted; for, as regards the stresses in simply supported beams, as Mr. Jonson has pointed out, the time yielding must result in a readjustment of abnormally high initial concrete stresses. When a revision of the theory is attempted, it must take into consideration, among other things, such conditions as the following: A beam simply supported and free to shrink, with an initial compression in the steel and the concrete uncracked; the same condition with the concrete cracked at rather wide and irregular intervals from the bending moments applied, also with the concrete thoroughly cracked throughout its length. Restrained beams, because of bending cracks over or near the supports, divide themselves into sections which may fulfill any or all of the foregoing conditions. Although all these conditions are neglected in the common theory, they cannot be neglected when an attempt is made to introduce the non-elastic deformations into the calculations.

In the deflection of beams the shrinkage and time yield play an important part. Deflections measured after several months are several hundred per cent. greater than the calculations from the common theory of flexure would indicate. Mr. Jonson's method of calculating deflections, if the value of f_s for the uncracked sections is used, gives results probably much nearer the true value than his moment calculations give the true stresses, because of the small influence of the occasional tension crack on the total deflection.

It is in regard to column stresses that these non-elastic deformations are of greatest importance. Using the notation of Mr. Jonson, and to re-state here some of his equations, we have the following:

f_r = initial compression in the steel due to shrinkage;
f_t = initial tension in the concrete due to shrinkage;
m = unit shrinkage;
E and n in their usual significance;
f_y = stress in the steel due to the load;
f_x = stress in the concrete due to the load;
f_s = combined steel stress = $f_r + f_y$.
f_c = combined concrete stress = $f_x - f_t$.

Mr. McMillan.

$$f_r = \frac{E\,m}{p\,n+1}, \text{ and } f_s = f_y + \frac{E\,m}{p\,n+1} \quad \ldots\ldots\ldots\ldots (1)$$

$$f_t = \frac{E\,m\,p}{p\,n+1}, \text{ and } f_c = f_x - \frac{E\,m\,p}{p\,n+1} \quad \ldots\ldots\ldots\ldots (2)$$

Now, the load applied to the column,

$$P = f_y\,p\,A + f_x(A - p\,A) \quad \ldots\ldots\ldots\ldots (3)$$

in which

$$f_y = f_x\,n \quad \ldots\ldots\ldots\ldots (4)$$

or

$$P = f_x\,A[1 + (n-1)\,p] \quad \ldots\ldots\ldots\ldots (5)$$

From these formulas can be obtained the actual stresses in columns designed by some of the accepted formulas of the day. For illustration, take two columns using 2% and 4% of vertical steel and 1½% of spirals. Calculated by the Joint Committee recommendations, the values of $\frac{P}{A}$ for these two columns would be 832 and 1 014, respectively. If calculated by the formula and unit stresses permitted in the Minneapolis Building Code:

$$P = 800\,Ac + 10\,000\,As + 2.4 \times 16\,000\,As'$$

the values of $\frac{P}{A}$ are 1 560 and 1 744, respectively.

Applying these formulas to these four columns, we get the actual unit stresses, f_c and f_s, shown in Table 5. These are worked out for two sets of values of Em and n, representing conditions that may frequently be expected.

TABLE 5.

$\frac{P}{A}$	p	$Em = 15\,000$, $n = 40$.				$Em = 21\,000$, $n = 50$.			
		f_x	f_y	f_c	f_s	f_x	f_y	f_c	f_s
832	0.02	467	18 680	300	27 000	420	21 000	210	31 500
1 014	0.04	396	15 840	166	21 600	343	17 150	63	24 150
1 560	0.02	876	35 040	710	43 370	788	39 400	578	49 900
1 744	0.04	682	27 280	450	33 040	599	29 500	310	36 500

From Table 5 it is seen that enormously high steel stresses may be expected in columns as conservatively designed as by the requirements of the Joint Committee, and that in columns in which large allowance is made for the spirals, stresses well above 30 000 lb. cannot be avoided. It should be noted that the shrinkage stress alone in these four columns varies from 6 000 to 10 500 lb. per sq. in. In support of the reasonableness of these calculations, the data on Fig. 12,

which show the results of measurements on columns of two buildings in service, are presented. Mr. McMillan.

In the first building the columns were 5 months old, and were carrying four floors and the roof when the observations were begun. Only a small quantity of dead load, such as partitions, interior finish, and equipment, has been added since. This is a university building, and, like others of its class, receives a very small proportion of the live load for which it was designed. The results of these observations are given in the curves marked Column 1 and Column 2. These

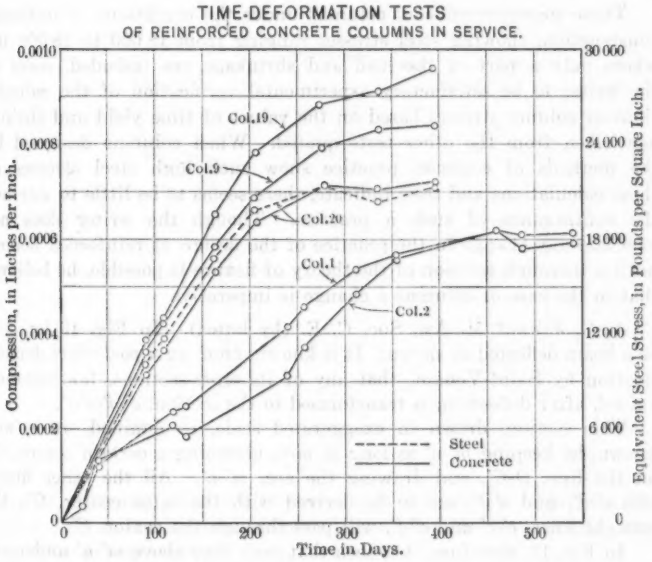

FIG. 12.

measurements were made at the surface of the column, but it is believed that measurements taken directly on the vertical rods would have shown the same results. The steel stress represented by these deformations is 18 000 lb. per sq. in., which is very noteworthy when it is considered that practically no dead or live load is included, and that at least some of the shrinkage must have taken place during the 5 months before the gauge lines were established.

The observations on the second building are given in the curves for Columns 9, 19, and 20. These were begun when the columns were about 2 months old, and were carrying only a portion of the full dead

Mr. McMillan.

load; the results, therefore, probably show a considerable portion of the shrinkage, as well as some of the dead-load stress. Like the previous building, very little live load comes to these columns, although it is provided for in the design. For Column 20, observations on both the concrete at the surface and on the vertical steel are shown; these, it will be noted, are in practical agreement. The steel stresses from the measurements on these three columns are from 21 000 to 28 000 lb. per sq. in., with the indication that there may be still some increase. These are basement columns, and as yet they have not been thoroughly dried out.

These measurements on columns under the conditions of ordinary construction, showing steel stresses ranging from 18 000 to 28 000 lb., where only a part of the load and shrinkage are included, seem to the writer to be satisfactory experimental verification of the calculations of column stresses based on the values of time yield and shrinkage taken from the other tests quoted. When columns designed by the methods of common practice show such high steel stresses as these calculations and tests indicate, there seems to be little to warrant the continuance of such a practice. Though the writer does not advocate any change in the practice of the design of reinforced beams, until a thorough revision of the theory of flexure is possible, he believes that in the case of columns a change is imperative.

Mr. Janni.

A. C. JANNI,* M. AM. SOC. C. E. (by letter).—In Fig. 13 let *A-B* be a beam deflected as shown. It is known, from an *a posteriori* demonstration by Saint-Venant, that any of its cross-sections, for instance, *c-d-e-f*, after deflection, is transformed to the section, *c'-d'-e'-f'*.

This section, drawn in exaggerated scale, is obtained, as is well known, by keeping *m'-n'* as long as *m-n*, assuming a certain center, *C'*, on the line, *O-C'*, and drawing the arc, *m'-n'*. All the other fibers, like *c'-d'*, and *e'-f'*, are to be derived with the same center, *C'*; the straight lines, *e'-c'* and *d'-f'*, will pass through the center, *C'*.

In Fig. 13, therefore, it is seen that each fiber above *m'-n'* undergoes a shortening which increases with its distance from *m'-n'*. The reverse—that is to say, the stretching of the fibers—happens for all fibers below *m'-n'*.

Poisson's coefficient, $\frac{1}{m}$, is simply the numerical translation of the physical phenomenon just described, and everybody understands that, in order to take it into account in an exact formula, it cannot be represented graphically very well, hence, tests have been made and have brought out various values for $\frac{1}{m}$, and these are not so far from $\frac{1}{4}$,

* New York City.

its theoretical value, as some seem to think. The tests mentioned, of course, were made by reliable scientists. Mr. Janni.

The general formula for the exact computation of stresses in beam deflection contains, in fact, the coefficient, $\frac{1}{m}$, as can be seen:

$$k = \text{Max.}\ \frac{M}{I}\left(\frac{m-1}{2\,m}\,h + \frac{m+1}{2\,m}\sqrt{h^2 + 4\,S^2}\right) \ldots\ldots(24)$$

where, M, I, m, and h have the same meaning as given in the paper, and S is the shear.

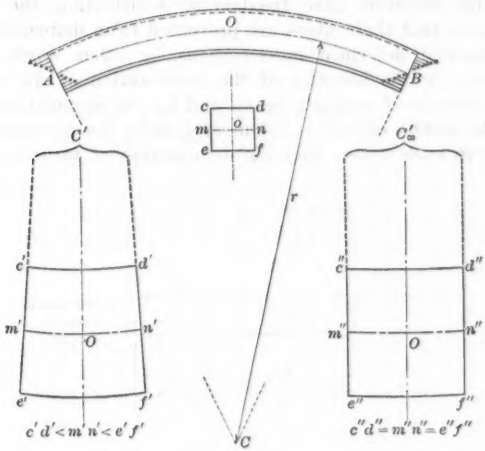

FIG. 13.

For every-day purposes, however, it is sufficient to verify the foregoing only at the top and bottom fibers and at the neutral axis, where it becomes, respectively:

$$k_1 = f_1 = \frac{M}{I}\,h, \text{ and } k_2 = f_2 = \frac{m+1}{m}\,S \ldots\ldots\ldots(25)$$

This shows that f_1, which we usually look for, is not a maximum, by any means, and that the indiscriminate use of this formula may lead to serious errors.

Fig. 13 shows, also, that, except for the neutral plane fibers, all the others of the cross-section are affected by Poisson's coefficient, and, therefore, the deflection of the beam is affected accordingly, although, for practical purposes, its influence may be ignored.

Now, if this same beam, A-B, is one of the ideal middle beams of a flat slab, its cross-section, c-d-e-f, on account of the continuity

Mr. Janni.

of the system of beams, cannot be deformed as the section, c'-d'-e'-f', was.

Then, we will have, as in Fig. 13, m''-$n'' = m'$-$n' = m$-n, and c''-$d'' = e''$-$f'' = m''$-n''; that is, the center, C', is at infinity and becomes C'_∞, and the fibers, c''-d'', e''-f'', will be parallel to m''-n'' as before, having, furthermore, a less pronounced curvature, which is the curvature of the ideal beam of the other system, crossing the first beam at that point.

We have before us, therefore, the shapes of the same cross-section of a deflected beam, the first by the hypothesis that the fibers of the beam during deflection have freedom of deformation, the second by the hypothesis that those fibers are prevented from deforming.

The enlarged deformed cross-sections, in other words, represent the difference in the behavior of the cross-section of the same beam by the hypothesis of a single beam, and by the assumption that this beam is the middle one of a system of parallel beams connected with each other in such a way that the deformation of its cross-section is prevented.

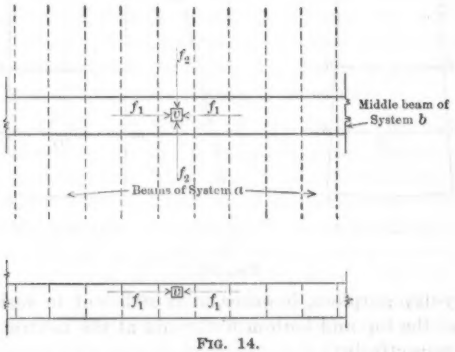

FIG. 14.

The absence of this phenomenon of deformation in this second case is essential to the behavior of the material in flat slabs, and, in order to take it into account in this investigation, it must be carried numerically in any formula the purpose of which is the finding of stresses in those ideal beams.

Accordingly, imagine that the ideal middle beam of System b is detached from all the beams of System a, Fig. 14, and is represented by v, an elementary cubical element of this beam.

Four forces will act on the vertical faces of this element. Two of these, f_1, are due to the deflection of the beam itself, and the other two, f_2, are due to the deflection of the ideal beam of System a, which, at that point, crosses the beam under consideration.

Mr. Janni.

Let e_1 and e_2 be the corresponding elastic deformations of the element, v, in these two directions; then,

$$e_1 = \frac{1}{E}\left(f_1 - \frac{1}{m} f_2\right) \ldots\ldots\ldots\ldots\ldots\ldots (26)$$

and,

$$e_2 = \frac{1}{E}\left(f_2 - \frac{1}{m} f_1\right) \ldots\ldots\ldots\ldots\ldots\ldots (27)$$

The deformation, e_2, must be zero, for the reason stated above.

We have, therefore,

$$f_2 = \frac{1}{m} f_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (28)$$

Hence,

$$e_1 = \frac{m^2 - 1}{m^2} \times \frac{f_1}{E} \ldots\ldots\ldots\ldots\ldots\ldots (29)$$

Now, if we consider two parallel contiguous sections of the beam, S_1 and S_2, as shown in Fig. 15, and a fiber, f, having a cross-section, dA, and a length, dx, the derivative of its work of deformation—assuming that the acting force, f_1, increases from zero to f_1—is given by

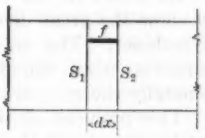

FIG. 15.

$$d\,L = \int \frac{1}{2} f_1 \times e_1 \times d\,A \times d\,x \ldots\ldots\ldots\ldots\ldots (30)$$

Substituting in this the value of e_1 from Equation (29), we have,

$$d\,L = \frac{1}{2} \times \frac{m^2 - 1}{m^2} \times \frac{d\,x}{E} \int f_1^2 \times d\,A \ldots\ldots\ldots\ldots (31)$$

but we know that,

$$f_1 = \frac{M}{I} h \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

hence,

$$d\,L = \frac{m^2 - 1}{m^2} \times \frac{M^2 \times d\,x}{2\,E\,I^2} \int h^2 \times d\,A = \frac{m^2 - 1}{m^2} \times \frac{M^2 \times d\,x}{2\,E\,I} \ldots (33)$$

Therefore, the work of deformation, as given by Equation (2), is justified.

In establishing the values of V_A, M_{AC}, and M_O, it has been assumed, for the sake of simplicity, that the beam, A-B, was loaded with the uniform load, w. This, of course, gives, for M_{AC} and M_O values a little higher than the actual ones, but the complexity resulting from assuming the parabolic law of loading would not be justified by the results in a practical application.

In order to leave no doubt as to the correctness of Equations (21), (22), and (23), giving the values of V_A, M_{AC}, and M_O, the method used in deriving them is given, as follows: Considering the general

Mr. Janni.

equation for the maximum moment in a single span, quasi-rigidly supported at its ends, and yielding vertically at one of its supports, and given by theory as

$$M_{max.} = M_A + \frac{V_A^2}{2\,w},$$

and applying it to the span, $A\ C$, Fig. 1, where, $M_A = 0$, we will have

$$M_{AC} = \frac{V_A^2}{2\,w},$$

As

$$M_C = V_A\,l_1 - \frac{w\,l_1^2}{2},$$

the vertical reaction, V_A, at A, will be

$$V_A = \frac{1}{2}\,w\,l_1 + \frac{M_C}{l_1}.$$

As stated in the Synopsis of the paper, the writer's intention was to show the great divergency of results obtained by the two different hypotheses. The use of the first assumption, namely, unyielding supports, when the designer has to deal with several panels, as is generally the case, is erroneous.

This problem, no doubt, is one of the most difficult, and a strictly mathematical solution, taking into account the peculiarities of this material of construction, seems to be impossible. This difficulty, however, cannot justify the silence of the building codes on this subject. A reasonable approximation is always possible, and the practical example in the paper gives an idea.

In view of all these considerations, Mr. Godfrey will see that the writer, in order to find the equation of the elastic line, in this particular case, could not use the customary expression,

$$\frac{d^2\,y}{d\,x^2} = \frac{M}{E\,I},$$

which, as Mr. Godfrey knows, is only approximate, although for everyday work it is reasonably satisfactory, since, as has been stated, it would not have brought out the principal physical phenomenon happening in the deflection of a slab.

From Equations (10) and (11), the writer derives a smaller value for D than from the equations obtained according to Mr. Godfrey's suggestion; this difference between the two results is caused simply by the difference in the conditions of the two deflections of the same beam by the two hypotheses.

In order to be clear, it may be stated that, in imagining the slab to be divided as has been done, two peculiar conditions have been created in those beams: The first is that the beams of System *a* help those of System *b* in carrying the load, and *vice versa*; hence the law of parabolic distribution of loading. The second is that these beams are not

free to deform crosswise; hence, the essential introduction of Poisson's coefficient in the equations. Mr. Jannf.

By taking into account, as far as possible, all the differences between plain, single-beam deflection and ideal, slab-beam deflection, we will get nearer the truth for all practical purposes.

Mr. Godfrey's remark, that the parabolic law of load distribution is enough, because it takes into account already the association of the ideal beam, is not quite correct.

In the case of the flat slab, as in other cases of reinforced concrete construction, the reason for the very small deflections usually observed —or the elastic deformations—must be found in the fact that the material (generally speaking) is being compressed or stretched in two directions, normal to each other, which condition is very favorable to the working capacity of the material, as it prevents important deformations.

It is a fact that Poisson's coefficient is purely theoretical, as far as its value, 4, is concerned, but the writer cannot agree with Mr. Godfrey regarding its unreliability for practical purposes, as some tests have given values which differ somewhat from 4, and this discrepancy is due, undoubtedly, to inevitable errors of readings, instruments, etc., besides the fact that isotropic bodies (and concrete may be regarded as such) cease to be isotropic when they are subjected to stresses in only one direction.*

If, as Mr. Godfrey states, some engineers are unwilling to use this coefficient, even in typical cases, this does not mean that it should be omitted from the theory. Those same engineers should know that they are using it, in any case, when they assume the working stress for steel in shear in relation to the working stress for bending, etc.

The value, 4, of Poisson's ratio is intended for isotropic bodies, it is true, but Mr. Godfrey's attention is called to the fact that, in this case, we have to deal with concrete and steel, and the steel (reduced to concrete according to the assumed value of $\frac{E_s}{E_c}$) is placed in the two directions along which it is consistently assumed that the forces are working. In other words, by reducing properly the steel in concrete, we obtain a solid wholly of concrete in the two directions which are of interest in this problem. This, of course, is an approximation, but, taking into consideration the great difficulties of the problem, the writer believes that it is permissible.

The tension in concrete, as Mr. Godfrey well states, undoubtedly plays its rôle in flat slab deformation; and this is also a reason that Poisson's ratio cannot be ignored in this problem.

The use of Equations (12) and (17), and those for the square slab, can be made by practical designers without caring very much how

* Grashof, "Theorie der Elasticität und Festigkeit," Berlin, 1878.

Mr. Janni.

they have been worked out, as is generally the case with formulas, as far as their mathematical derivation is concerned.

The writer will not discuss the question of priority in the method of treating a slab made up of several beams lying in two directions, as mentioned by Mr. Godfrey. In adopting this treatment, the writer never claimed originality.

Starting with the foregoing assumption, in the case of a flat slab design, the fact that, in a square slab, each middle strip at its middle square unit carries one-half the uniform load is self-evident, and the result given by Equation (12), when $l = l_1$, namely, $\alpha = \frac{1}{2}$, is a check of that equation, rather than a result.

To assume that the end moment, M_p, is two-thirds of the fixed-end condition, as has been done by the writer, is similar to—and with nearly the same degree of approximation—that which is made for fixed-end beams, in order to take care of the one-panel loading condition.

In order to demonstrate this statement, attention is called to the formulas, for instance, for the square slab case. There the numerical coefficients should be $\frac{1}{21.33}$ and $\frac{1}{26.94}$ (for a square slab, however, the writer has thought it expedient to state these values in round figures, namely, $\frac{1}{21}$ and $\frac{1}{27}$, in order to memorize them more easily), and those actual values, of course, must be taken for the following demonstration.

According to the accepted rule, the moments for a beam with assumed fixed ends are computed on the basis of the coefficients, $\frac{1}{10}$ and $\frac{1}{12}$ (respectively in the middle of the span and on the supports). These two coefficients give the following results:

$$\frac{1}{10} + \frac{1}{12} = 0.183 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (a)$$

$$\frac{1}{12} : \frac{1}{10} = 0.833 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (b)$$

and the coefficients resulting from the writer's assumption, remembering that these coefficients enter twice into the calculation of the moments for the same panel, will give:

$$2\left(\frac{1}{21.33} + \frac{1}{26.94}\right) = 0.168 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (a')$$

$$\frac{1 \times 2}{26.94} : \frac{1 \times 2}{21.33} = 0.791 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (b')$$

Mr. Janni.

From a comparison of the foregoing equations, (a) with (a') and (b) with (b'), it will be seen that, even though the writer's assumption was "very rough", it would not be any rougher than that usually made for fixed-end beams. Mr. Godfrey's remark, therefore, may be regarded as a little precipitate.

It is true that a slab supported by girders on all edges does not find many users, but this paper is simply the result of the writer's designing of reinforced concrete floors, built years ago, according to these lines, by the expressed wish of the owner, and it was thought that the results might be useful in giving some hint, as stated at the end of the paper, as to a correct solution for flat slab floor design.

Undoubtedly, as Mr. Godfrey remarks, we are badly in need of serious tests in this line, but the writer is afraid that this will never be accomplished, as business has taken such a firm hold on the whole question.

Mr. Goodrich's contribution shows clearly that he understands fully the spirit of the paper. The writer has had no intention of adding any formulas to the more or less empirical ones already in existence, many of them misleading; but his aim has been to show the great influence of the elastic displacements of the supports on the values of the bending moments.

It has not been without a great deal of hesitation that the writer has undertaken to reply to Mr. Jonson. The only reason which prompted him to devote some time and space to this purpose has been the fact that his silence concerning Mr. Jonson's remarks might be interpreted as an acceptance of his statements.

Leaving to Mr. Jonson the responsibility for his statement that "the moment of inertia is not only a constant, but also a function", the writer must say that, when Mr. Jonson brings up the well-known question of the variability of the inertial moment of the reinforced concrete section, he shows quite clearly that he ignores the fact that this moment of inertia, as we find it, and as it was agreed on years ago, must not be intended for each and every stage of the deflection of the beam.

The position of the neutral axis in the cross-section of a reinforced concrete beam, and, consequently, its moment of inertia with respect to it, are purely conventional, as long as the stresses in the concrete and steel are below or above the stresses calculated, but, as soon as the stresses actually in the beam approach those calculated at that section, the actual position of the neutral axis is very close to, if not coinciding with, that assumed. However, if there is any discrepancy, the usual assumptions, in determining the position of the neutral axis, are on the safe side, and this must be so because the tension in concrete is disregarded.

Mr. Janni.

The most important matter in designing a building of reinforced concrete or any other material is not strictly the exact correspondence between calculated and actual stresses, but, indeed, the safety of the building itself.

Designers know very well that the methods used in designing any kind of a building cannot be of such precision that they can be applied, for instance, to the construction of a Bauschinger's Spiegelapparat measuring $\frac{1}{5\,000}$ mm. of deformation.

Neither is it practical to design and construct buildings for ordinary purposes in the same way as beams and floor panels would be designed and built in a laboratory for scientific research.

Mr. Jonson's attention is called to the work done by the French Commission,* which was formed 16 years ago, and, after 6 years of very exhaustive study, published the results. Incidentally, in the writer's opinion, this work so far has been unsurpassed, either in America or Europe.

Mr. Jonson will find there that the question of the variability of E_c has been thoroughly investigated. He will also find that, in addition to all the causes bearing on this variability, mentioned in that work and repeated now by him, the Committee investigated the variation of this modulus due to the method of concreting (vertical or horizontal, post or beam); or due to the personal equation of laborers, etc.; and, finally, he will find that, after taking into account all possible causes, the value of $\frac{E_s}{E_c}$ was not decided on as a real constant quantity, but it was agreed to assume 8 and 15 as minimum and maximum limits, respectively; and this range of values for $\frac{E_s}{E_c}$ has been generally recognized as right, even after later tests and investigations.

The designer may make the choice—not capricious, but judicious—of the proper value of $\frac{E_s}{E_c}$, according to the circumstances. The misjudgment of the designer or of some building law, in the choice of this value, Mr. Jonson will agree, cannot be imputed to theory.

The question of shrinkage in concrete, as affecting the working stresses in a beam, which, from Mr. Jonson's discussion appears to be a discovery brought up by him for the first time, is also old; in fact, on page 371 of the aforesaid work of the French Commission. the first two questions which the Commission proposed to investigate, were as follows:

First.—*"Quelle est l'importance du phénomène du retrait?"*

* Commission du Ciment Armé: Expériences, Rapports, et Propositions, Instructions Ministérielles Relatives à l'Emploi du Béton Armé, Paris, 1907.

Second.—*"Doit-on en tenir compte dans les calculs de résistance?"* and, on the same page, the following answer is found: Mr. Janni.

"Tout en affirmant le fait incontestable qu'est le retrait, la Commission a proposé d'autoriser les Ingénieurs à n'en pas tenir compte, lorsq'ils pourront justifier qu'il ne saurait en résulter d'inconvénients et il parait en être généralement ainsi pour les supports et les planchers intérieurs des bâtiments dont les dimensions horizontales ne sont pas grandes."

The date of this report, and these quotations, will dispose of any possible doubt as to whether Mr. Jonson, having looked into "the entire theory on reinforced concrete" and having found it "rather crude", has brought out a new and important question.

Mr. Jonson, the writer is sure, must realize that the guesswork advocated by him in predicating the position, the direction, the number, and the size of cracks in a restrained reinforced concrete beam, does not and cannot interest an engineer during a serious technical discussion.

As he is attempting also to introduce a new method of designing, in order to take into account the shrinkage, as he says, it will not be amiss to show that this method is wrong.

To start with, Mr. Jonson says "All calculation of reinforced concrete made on the assumptions that the ratio, n or E divided by E_c, is a constant are unreliable", and rather inconsistently he proposes the use of formulas in which this very ratio appears, with the addition of a certain quantity, m, the introduction of which will be discussed later, and which would be an additional uncertain factor in designing.

Apart from many other considerations, however, it can be stated that, from what Mr. Jonson says and proposes to do, it is clear that he ignores that theory has a formula, as follows:

$$f = \pm \frac{N}{A} + \frac{M}{I} h$$

in which f is the maximum allowable stress; N, the compressive or tensile stress along the beam; A, the sectional area; M, the external moment; h, the distance between the farthest fiber and the neutral axis; and I, the inertial moment of the section.

Applying this formula to a reinforced concrete beam, when it is necessary at all, the stress in concrete and that in steel can be computed, remembering that, for practical purposes and for the sake of brevity, the second term of the second member, for reinforced concrete sections, is replaced by a simpler one.

Assume a 20-ft. reinforced concrete beam, with a section of 24 by 14 in., with 3.36 sq. in. of steel reinforcement; and assume that its length is kept constant, so that it is under the full tension caused by the unyielding of its ends during its setting.

Mr. Janni. As the coefficient of the shrinkage is known to be $\frac{1}{2\,000}$, this beam, after setting, is actually under a tensile strain of

$$\frac{20}{2\,000} = 0.01 \text{ ft.}, \quad 0.01 = \frac{N \times 20}{2.33 \times 144\,000}$$

$$\frac{N}{2.33} = 71.856 \text{ tons per sq. ft., or } 998 \text{ lb. per sq. in.}$$

so that each square inch of its concrete cross-section would be under the enormous tension of 998 lb.

Concerning the steel now, it is observed that the rise in temperature which takes place during the setting of the concrete, will increase the length of the reinforcement. This increase, which is the cause of tension in the steel during the first few weeks of hardening of the concrete, diminishes gradually with the further shrinking of the concrete, and, finally, becomes compression, but its value is negligible for all practical purposes.

As it was assumed, however, that the ends of the beam are absolutely unyielding horizontally, it must be assumed (as a matter of consistency) that the increased length in the reinforcement is kept constant.

Assuming, say, 25° Fahr. as the rise in temperature during setting, and assuming 0.0000067 as the coefficient of expansion for the steel, the tensile stress in the reinforcement will be 5 000 lb. per sq. in.

Now, if the bending moment acting on this beam were 1 195 444 in-lb., we would have 998 lb. per sq. in. compression in concrete, and 19 343 lb. per sq. in. tension in steel.

Adding algebraically these stresses to those found in the case of plain tension, we will have 0 lb. per sq. in. compression in concrete, and 24 343 lb. per sq. in. tension in steel.

Furthermore, with a moment $M = 679\,800$ in-lb., we will have the total stresses in the concrete and steel as follows: minimum tension in concrete 431 lb. per sq. in., and tension in steel 16 000 lb. per sq. in.

These results, which are strictly correct, according to the assumption made (horizontally unyielding beam ends), need no further comment.

Everybody, even those not thoroughly familiar with concrete construction, knows that, in common cases, the unyielding of the beam ends is not possible, due to the elastic deformation of the whole construction, by which, providentially, the entire system takes up a condition of reciprocal adjustment among its various elements.

The absence of any perceptible crack in the great majority of reinforced concrete beams clearly supports this assertion; therefore, it

must be assumed that, if there is any initial tension, it must be quite negligible in ordinary cases. Mr. Janni.

If, however, peculiar conditions of the building make it advisable to take into consideration the tension due to shrinkage, then the theory has already everything that is needed by the designer for this purpose, as has been shown.

In order to prove further that Mr. Jonson's theory is not only unnecessary, but is altogether wrong, attention is called to the following facts:

For the action of the axial tension (or compression) and that of a moment on a solid, may be substituted the action of an eccentric tension (or compression), so that, admitting the necessity seen by Mr. Jonson of taking into account in all cases the effects of shrinkage, the beam is to be regarded as a post (with eccentric negative compression).

Everybody knows that the position of the neutral axis, that is, the value of k, in this case, is given by an equation of the third degree, or, more speedily, by a certain graphical construction, but Mr. Jonson obtains for k an equation of the second degree and one of the first degree (his Equations (2) and (7)), *ad libitum*.

It can easily be seen that the diagram, Fig. 3, is drawn incorrectly, and therefore that the values of k are also incorrect.

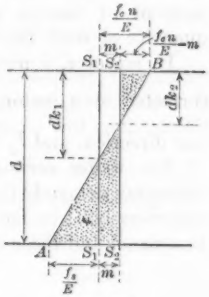

FIG. 16.

That diagram being incorrect (as will be demonstrated), Mr. Jonson's Equation (1) is incorrect, and so are all the succeeding equations which are derived either from his Equation (1) or from Fig. 3.

Let S_1-S_1 (Fig. 16) be the section of the beam under consideration; this section is under the action of a bending moment, the diagram of which may be represented by a straight line, A-B, where S_1-$B = \frac{f_c n}{E}$ is the maximum compressive stress, and A-$S_1 = \frac{f_s}{E}$ is the maximum tensile stress (or their proportional variations of length), and the value of k_1 can be found by the usual methods. (Analytically, the value of k_1 is given by an equation of the second degree.) The axial tensile force, acting on the section, S_1-S_1, will simply bring that section to a parallel position, S_2-S_2.

The diagram, therefore, of these two combined actions, will be represented by A-S_2-S_2-B-A, and the value of k_2, which corresponds to k in Fig. 3, is given, as stated previously, by a third degree equation only. A comparison of Fig. 16 with Fig. 3 will quickly show the mistake.

Mr. Janni.

Having demonstrated that the theory advanced by Mr. Jonson is "fundamentally wrong", and that the real theory is quite able to take care of shrinkage when that is necessary; and after having called attention to the fact that this problem is not new, as it was studied exhaustively 16 years ago, the writer thinks it expedient to disregard all Mr. Jonson's other remarks in this line, for the sake of brevity, and also because the statements and results, being on a false premise, must be wrong, and to reply to his discussion having direct bearing on the paper.

The writer agrees with Mr. Jonson that the moments of inertia cannot be the same in both directions, because the steel is not at the same altitude in the two systems; but if Mr. Jonson thinks that the percentage of steel is very small, and its size also, he will see that this is an approximation which may be allowed. In computing the moment of inertia of a reinforced concrete section, with a small quantity of steel, the steel may be disregarded entirely.

If, however, a more exact result is desired, Equation (12) may be corrected by a factor, $I = \frac{I_1}{I_2}$ where I_1 is the moment of inertia in one direction, and I_2 that in the other.

The writer certainly cannot agree with Mr. Jonson's statement: "economy demands that less reinforcement be used longitudinally than transversely". In fact, the moments at the center of each middle beam in a panel and those on the supports are tied together by the relations:

$$\frac{M_O}{M'_O} = \frac{l^2\,(7 + 43\,\alpha)}{l_1^2\,(50 - 43\,\alpha)}$$

$$\frac{M_P}{M'_C} = \frac{l^2\,(1 + 4\,\alpha)}{l_1^2\,(5 - 4\,\alpha)}$$

As stated in the paper, the value of α may vary between $\frac{1}{2}$ and 1, and inspection of the expressions mentioned shows that the maximum moments are on the shorter span; therefore, a larger quantity of steel must be used in that direction. Thus "economy demands" nothing; it is only a matter of results obtained by theory.

Mr. Jonson says:

"The author's method implies the assumption that all moments are at a maximum when the entire floor is covered by the live load. This assumption is erroneous."

Then he gives the well-known "recipe" for obtaining the maximum moments in continuous beams, which he thinks the writer should have followed in order to be correct.

Mr. Janni.

Evidently, Mr. Jonson ignores the fact that the usual "recipe" does not hold good when the supports are elastic, that is, when they are displaced vertically under the loading. In fact, let Fig. 17 represent the middle beam under consideration in the paper, and suppose that C and D are unyielding; then, assuming that only the span, C-D, is loaded, and applying the theorem of three moments* to the supports, A, C, and D, and remembering that the moment at A is zero, and that the moments at C and D, by symmetry, are equal, we will obtain, with the same unit load as in the application treated before:

$$188 \text{ lb. (live load)} = 300 \text{ lb. (total load)} - 112 \text{ lb. (dead load)},$$

$$M_C = 5\,414 \text{ ft-lb.}$$

and, therefore, the moment, M_O, at the center of the span, C-D, will be given by:

$$M_O = \frac{1}{8} \times 188 \times (24)^2 - 5\,414 = 8\,122 \text{ ft-lb.}$$

If these results are compared with those obtained by the writer, when he took into consideration the yielding of the supports, C and D, as must be done, the value of Mr. Jonson's remark will undoubtedly be realized.

Incidentally, it may be noted that his statement concerning the most critical condition of partial loading is the very thing brought out by applying the theorem of three moments to a continuous beam, although Mr. Jonson states, a few lines before this remark, that "the theorem of three moments cannot be applied to reinforced concrete, nor any other method which deals in deflection components." In this, assuredly, there is also lack of consistency.

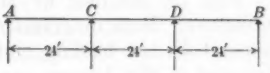

FIG. 17.

It is difficult to understand why, as Mr. Jonson states (the slab being regarded as having fixed edges, and its elastic curve, consequently, being a reversed one), the law of variation of loading "is more closely approximated by a straight line from end to middle than by a parabola"; indeed, it is the writer's opinion that this remark is altogether whimsical. In order to support this statement, however, Mr. Jonson makes the following remark: "The latter [the parabolic law] would be the proper approximation for a non-continuous slab merely supported along its edges".

As a matter of fact, if the parabolic law is the proper approximation for a non-continuous slab, it must be also for a continuous slab. In fact, let A-B-C (Fig. 18) be the parabola of bending moments for the beam, A-C, with the assumption that this beam is supported freely at its ends, and that the parabolic law of loading is adopted.

* The propriety of applying this theorem will be discussed later.

Mr. Janni. If it is supposed now that its ends are fixed, the diagram of bending moments will be obtained, as shown by *A'-B'-C'-E-D*. The line, *D-E*, is to be determined by proper methods, and the parabola, *A'-B'-C'*, is determined by the assumption that the beam, *A'-C'*, is freely supported; therefore, this parabola must be the same as *A-B-C*.

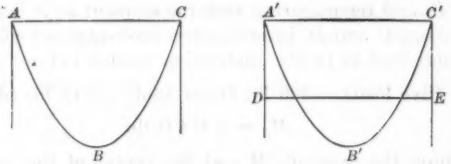

FIG. 18.

This question being settled, on the basis of theory, the writer thinks it expedient, in order to justify his assumption of the parabolic law, instead of the linear law, to show the behavior of the deformed axis of the same beam, subject to both a parabolic-law and a linear-law loading.

Fig. 19, obtained by Mohr's method, gives all the information necessary. Both diagrams represent the same beam, first loaded with a parabolic-law loading and then with the same total load, but distributed, as Mr. Johnson says it should be.

The parabola, *C-O-D*, represents the parabolic law of distribution of the loading, and *E-O-F*, the other assumption of distribution.

By using the same scale in the graphical constructions of the moment diagrams for both hypotheses, by taking the same polar distances in both cases and in each instance, we obtain the same distorted scale for the two diagrams representing the deformed axis of the beam, and, therefore, a comparison between them is made at a glance.

If reliable tests were made, it would be possible to state something definite concerning the degree of approximation of the two assumptions of loading; since, however, such tests are lacking, it may be said that the writer's assumption, already used by others, on the hypothesis of loading, is, at least, as good as that suggested by Mr. Jonson, without substantiating it in any way.

Incidentally, it will be remarked that, in assuming the parabolic law, the writer followed the very method just shown and found no reason to change what already had been done.

Mr. Jonson, it seems to the writer, is rather concerned that the paper, in some points, does not convey his (Mr. Jonson's) ideas, but the writer's ideas, and, accordingly, he attempts to correct what he thinks is erroneous.

Mr. Janni.

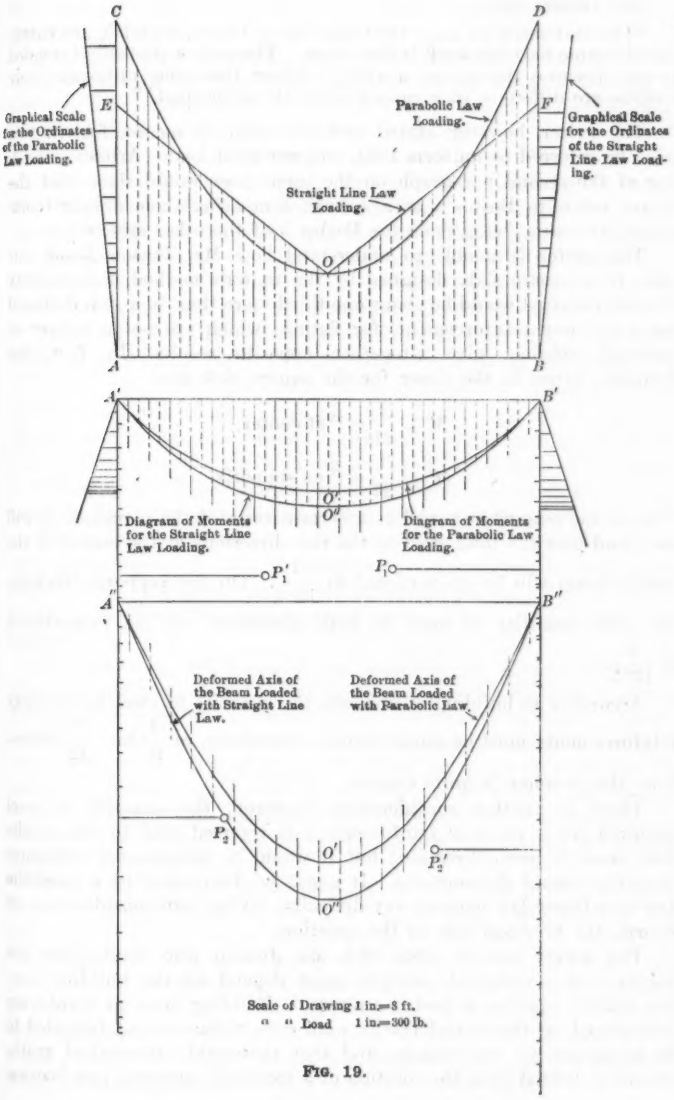

FIG. 19.

Mr. Janni.

Mr. Jonson says:

"The statement on page 1690 that 'these beams, *a* and *b*, are carrying the same uniform load' is erroneous. The author probably intended to say 'because the beams, *a* and *b*, deflect the same, although their lengths are different, they cannot carry the same load.'"

The writer, however, stated correctly what he meant, for, in this case, he referred to uniform load, and not total load. Attentive reading of the second paragraph on the same page would show that the writer refers to Beams *a* as a system, comparing them among themselves; the same being done for Beams *b* of the other system.

The writer is unable to understand how Mr. Jonson found out that, in a square slab, designed by the writer's method, the quantity of steel required would be about one-third more than in a slab designed for a one-way reinforcement, for figures, which are not a matter of personal opinion, give altogether opposite results. In fact, the formulas given in the paper for the square slab are:

$$M = \frac{1}{21} w l^2 \text{ at center,}$$

$$M' = \frac{1}{27} w l^2 \text{ on supports.}$$

Taking the quantity of steel as a certain ratio of the moments, it will be found that the total steel in the two directions at the center of the middle beam will be proportional to $\frac{1}{10.5}$. On the supports, likewise, the total quantity of steel in both directions will be proportional to $\frac{1}{13.5}$.

According to building ordinances, the quantity of steel for one-way reinforcements must be proportional, respectively, to $\frac{1}{10}$ and $\frac{1}{12}$; therefore, the economy is quite evident.

There is another consideration, however; the quantity of steel required for a two-way reinforcement is referred only to the middle 1-ft. beam in each direction; but it would be progressively excessive in going toward the supports. It might be diminished by a parabolic law or a linear law without any difficulty, taking into consideration, of course, the practical side of the question.

The writer cannot agree with Mr. Jonson who thinks that the solution of a technical question must depend on the building law; the writer's opinion is just the reverse. Building laws, as a rule, are formulated on theoretical truths, and, even then, are not intended to be textbooks, by any means; and that thoroughly theoretical truths should be barred from the solution of a technical question, just because

they might conflict with some stale building ordinance limitations, is somewhat ridiculous. Mr. Janni.

By far the most interesting part of Mr. Jonson's discussion is that which deals with a certain graphical construction which, according to his judgment, should be followed, in order to avoid "the illegitimate use of the theorem of three or of four moments."

In order to be clear, the writer will devote a few words to the use of the theorem of three moments, and will demonstrate, incidentally, that its use in the case considered by him in the paper, was quite legitimate. He will then deal with what Mr. Jonson calls "the theorem of four moments" and its quite correct application to reinforced concrete girders; finally, the graphical method proposed by Mr. Jonson will be taken up, with some of its astounding consequences.

Evidently, when Mr. Jonson says that, on account of the variability of the moment of inertia in a reinforced concrete girder, the application of the theorem of three moments is "illegitimate", he either forgets or ignores two fairly important facts: The first is that the theorem of three moments may be extended legitimately to the case in which the moment of inertia of a girder is variable; and this is done by the theory of virtual work. This theorem has progressed somewhat since Clayperon, in 1857, first gave his simplified solution of this problem.

The second fact—and this is the ordinary case in reinforced concrete construction—is that, in the case of supports on the same level, the last term of the equation of the theorem of three moments, which would bring forth the moment of inertia of the cross-section, disappears.

The values of the moments on supports, for girders of various spans, are already calculated in engineering handbooks, and, of course, without any moment of inertia to be substituted in them. Hence, admitting only for a moment that a reinforced concrete girder is freely supported at several points of its length, no matter whether the moment of inertia is constant or variable, and no matter also whether or not its supporting points are on the same level, the equation of three moments may be used legitimately; this is as far as the general theory of this theorem applies.

The writer will now justify the use of this theorem in the paper: It will be noticed that the beam, *A-C-D-B*, rests freely on four supports, since the sections of this beam on the supports, *A* and *B*, are admittedly free to have whatever very small rotation may take place on account of the deflection of their own spans, and since the supports at *C* and *D* are not less loose, according to the temporary assumption, than at *A* and *B*. One should not take seriously the question of "torsional resistance" of the supporting girders at *C* and *D*, especially when, as it is assumed, the beam, *A-C-D-B*, is unloaded.

Mr. Janni.

Furthermore, the theorem of three moments has been used in order to find M''_C, that is, the moment at C when the assumed vertical displacement takes place, and this quite independently of any hypothesis of loading for the beam itself. In other words, having the supports, A, C, D, and B, on the same level, and the beam unloaded, if, for some reason, the supports, C and D, give way vertically, a certain moment will appear at C and D; this is the moment found by the writer by a quite legitimate use of the theorem of three moments.

Mr. Jonson directs attention to what he calls "the theorem of four moments", and gives information concerning a paper presented by him before this Society dealing with the subject. The writer has examined the paper referred to and finds that it deals with the analytical solution of the problem of finding the moments in a girder stiffly connected to its supports. This problem was treated by W. Ritter* in 1900; Mr. Jonson's paper appeared in 1905. It can be added, also, that some diagrams in this latter paper are incorrect. The reader may draw his own conclusions.

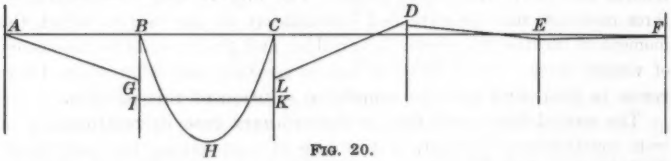

FIG. 20.

A few words will now be devoted to the solution of the problem involved in the case of a girder stiffly connected at various points of its length.

There are two different and mathematically correct solutions of this problem. One is a graphical solution by the method of the ellipse of elasticity, and the other is analytical, following Ritter's theory on this subject, as published in the book quoted.

For practical purposes, the graphical method, which is applied in a manner similar to that used in the case of continuous elastic arches resting on elastic piers†, is (contrarily to what happens in the case of an arch system) to be discarded when the elastic system has more than two spans.

Ritter's analytical method may be followed in every instance. Evidently, the moment developed by the post will be equal to the difference between the two moments, one at the section of the girder immediately on the left, and the other at the section immediately on the right, of the support. This difference between each couple of the similar sections at each support causes, at each of these points, a sudden vertical step in the diagram of the moments, as is shown in Fig. 20.

* W. Ritter, "Der Kontinuirliche Balken", 1900.

† G. A. Hool, "Reinforced Concrete Construction", Vol. III, 1916.

Mr. Janni.

This calculation, in the case of a girder, as it has been assumed, is not a luxury of theory; it is purely a necessity of design. It should be made in order to take into account the real conditions of the elastic system. It is the aim of theory to simplify things as much as is consistently possible, but when a problem involves methods, which, perhaps, are still a little outside of the every-day routine designer's reach, engineers cannot sacrifice their pride to "rules-of-thumb". To disregard the moments in posts stiffly connected to a girder (and usually concrete girders are in this condition when supported by concrete posts) is an error of design which should be avoided.

The last point which the writer will take up is the graphical construction suggested by Mr. Jonson for the design of a three-span continuous girder.

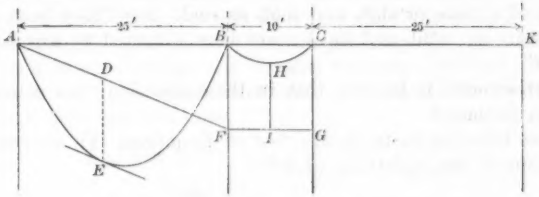

FIG. 21.

Fig. 21 is simply a representation of the graphical construction suggested by Mr. Jonson, and transmitted to the writer by him.

On page 1709, Mr Jonson states:

"The correct method of calculating such a girder is much simpler than by the illegitimate use of the theorem of three or of four moments. Construct a static moment diagram on each span as if it were discontinuous. Then divide the diagram of the long span by a straight line in such a way that the positive moment at the middle of the suspended span is numerically equal to the negative moment in the double cantilever over the column. Then draw a horizontal line representing the negative moment across the middle span, and the area included between this line and the first moment curve will be the true moment diagram. The point at which the first straight line intersects the moment curve of the side span is, of course, the point at which the reinforcement should cross the center line."

It is granted that this graphical solution is "simpler" than the application of the theorem of three moments, or that which takes into consideration the moments due to the post connection; unfortunately, however, this is not a solution, but is something never heard of before. Suppose that the span, *A-B*, remains constant in length, and that the length of the span, *B-C*, increases gradually. According to this graphical construction, the moment at *B* will be always the same (that

Mr. Janni.

is, *B-F*), since the post, *B*, does not move; therefore, no matter how long *B-C* becomes, its moments at its supports will be constant, and their value will be controlled solely by the preceding span, *A-B*.

Mr. Eddy's discussion may be divided into two parts: In the first he states that the fundamental equations of the paper are wrong, since they do not agree with Equations (1) of his discussion, which, as he says, are the equations for a flat slab in their most general form. In the second part he remarks that, since the mathematical working out of the formula is also wrong, the results do not deserve great confidence.

Before proceeding any farther with this part of the discussion, the writer wishes to ask Mr. Eddy whether he is sure that his Equations (1), as interpreted by him, are the correct moment equations for the flexure of a plate or slab, and that, as such, they "have been accepted universally as valid, and have never been disputed by any competent writer?"

Furthermore, is he sure that in these equations due consideration is given to shear?

If we take, for instance, the first of Equations (1), we note that it is the sum of two equations, namely:

$$M_1 = \pm E I \frac{d^2 z}{d x^2}$$

$$- K M_1 = \pm E I \frac{d^2 z}{d y^2}.$$

The first is the differential equation of the elastic line due only to the longitudinal deformation, by compression and tension, in the various fibers of the beam, caused by the moment, M_1; the second equation gives the algebraic additional deformation of the elastic line due to the cross-deformation of the same longitudinal fibers of the beam, as is shown by the presence in this equation of the ratio, K, and of the expression, $\frac{d^2 z}{d y^2}$.

Since, as is very well known, the first of these two equations is quite independent of shear, Mr. Eddy should have devoted a few words to the justification of his statement that, at least, the second equation contains shear. It would be very interesting to see how Mr. Eddy could discover the shear in an equation in which the second member is purely a differential geometrical expression multiplied by a numerical constant, E (which constant refers only to compression and tension), and by a geometrical (or numerical) quantity, I, and the first member contains a certain numerical quantity, K, due to tension or compression, and a moment, M_1, has nothing to do with shear.

Mr. Janni.

An assertion such as that made by Mr. Eddy is very grave, and cannot be passed without being pointed out.

As a matter of fact, Equations (1), with the interpretation given by Mr. Eddy, are quite independent of each other as long as some kind of relation among the expressions, $\frac{d^2 z}{d x^2}$, $\frac{d^2 z}{d y^2}$, is not given. They represent the deflections of two beams which deflect, one under the action of the moment, M_1, and the other under the action of the moment, M_2, and this, contrary to what Mr. Eddy has asserted, is quite independent of shear; therefore, they are not general.

These beams, on account of the same notations, x, y, z, might be supposed to cross each other normally at some point of their spans.

Assuming, as it is legitimate to do, that they be applied to the ideal beams in our case, the writer will show that the fundamental equations of the paper agree with the equations as given by Mr. Eddy, and that the mathematical working out of the formulas, derived from the equations given by the writer, is correct. In fact, taking, for instance, the first of these two equations,

$$(1 - K^2)\, M_1 = \pm\, E\, I \left(\frac{d^2 z}{d x^2} + K \frac{d^2 z}{d y^2}\right)$$

we see that the term, $K \frac{d^2 z}{d y^2}$, of the second member refers entirely to the vertical deflection of the ideal beam, due solely to the lateral (or horizontal) deformation of the cross-section of the ideal beam in that part of the slab.

This lateral deformation has been logically stated to be zero, on account of the working conditions of the ideal beams of System a in connection with those of System b, therefore this equation, applied to the middle beam of one of the two systems, becomes:

$$(1 - K^2)\, M_1 = \pm\, E\, I \frac{d^2 z}{d x^2}.$$

This being the deflection at the end of the cantilever, the work of deformation of the entire cantilever, between the limits, 0 and $\frac{l}{2}$, will be given by:

$$L = \int_0^{\frac{l}{2}} \frac{1 - K^2}{E\, I}\, M \times \frac{1}{2}\, M \,.\, d\, x = \int_0^{\frac{l}{2}} \frac{1 - K^2}{2\, E\, I}\, M^2 \,.\, d\, x.$$

Substituting for K its classical form, $\frac{1}{m}$, we obtain,

$$L = \int_0^{\frac{l}{2}} \frac{m^2 - 1}{m^2} \times \frac{M^2 \,.\, d\, x}{2\, E\, I},$$

which is identical with Equation (2) in the paper.

Mr. Janni.

It is demonstrated, therefore, that Equation (2) is correct, and, of course, agrees with the equations given for this case of deflection. In exactly the same way we might proceed for the other equation of the system given by Mr. Eddy, when it is applied to the other middle beam of the other system of beams. Having demonstrated the correctness of the writer's Equation (2), it follows that Equations (10) and (11) are correct also.

The writer certainly is indebted to Mr. Eddy, as his erroneous remark has given the writer the opportunity of deriving his Equation (2) in an entirely different way.

It is rather interesting to observe that, though Mr. Eddy had found out that "The fundamental equations used by Mr. Janni differ from these [Equations (1) of Mr. Eddy] in reality only in one point, namely, by suppressing and leaving out the last term of each of them", he did not stop to think about the mathematical meaning of this suppression, but confined his investigation purely to a clerical check. He says: "Mr. Janni in his mathematical work has chosen to develop the subject by attempting to modify and apply the equations of Professor Fraenkel for beams. * * *."

This remark is preposterous. As a matter of fact, there are no such equations as "equations of Professor Fraenkel" on this subject, and the writer is very much surprised at the statement.

What Mr. Eddy calls "equations of Professor Fraenkel" are merely the equations on the deflection of a beam in their most general form, derived by applying the law of virtual work, which any good book on the subject reports, just to show that it is possible, by that method, to generalize the equations on deflection, in the same way as the theorem of three moments by this same law has been generalized and made applicable in the case, for instance, of a variation in the cross-section of a continuous beam.

Mr. Eddy, in making this statement, is crediting Professor Fraenkel with a paternity of which the latter never dreamed.

Mr. Eddy says:

"These errors in Equations (1) and (2) are curiously so related, the one to the other, that Equation (3) is the same as would be obtained were the alterations just pointed out made in Equations (1) and (2)."

It has been already demonstrated that Equation (2) is correct, and it will be shown presently that this is the case also with Equation (1).

Among the most remarkable theorems demonstrated by the law of virtual work, there is one, by Castigliano,* called "Theorem on the

* Castigliano, "Teoria dell' equilibrio dei sistemi elastici e sue applicazioni", Torino, 1879. The original Italian work is not available, but there is a French translation.

derivative of work". This theorem has demonstrated the correctness of the expression: Mr. Janni.

$$D = \frac{d\,L}{d\,F}$$

It may be explained as follows: The displacement, D, of a point of an elastic system along the direction of an ideal force acting on this point, is given by the partial derivative, with respect to the applied ideal force, of the work of deformation of the entire system. Incidentally, it can be safely stated that this theorem and the peculiar form of the foregoing expression are familiar to anybody who has had even the slightest acquaintance with the theory of virtual work. It is hoped that this is enough to substantiate the strict correctness of Equation (1), without inserting in these conclusions a couple of pages of theory taken from some textbook.

Mr. Eddy furthermore states that there is no proof that the equation, $f\,\frac{I}{h} = (1 - K^2)\,M$, is given by any known theory. It will be demonstrated that the theory, on the writer's assumptions, gives this equation as correct. In fact, taking the equation, $e_1 = \frac{m^2 - 1}{m^2} \times \frac{f_1}{E}$, already given herein, and observing that $E\,e_1 = f$ and $f_1 = \frac{M\,h}{I}$, we may write:

$$f\,\frac{I}{h} = \frac{m^2 - 1}{m^2}\,M$$

which demonstrates that the general equation for the deflection has been given correctly by the writer. Mr. Eddy can hardly expect to have reported by theory all possible equations for all possible hypotheses; it is very often the task of the engineer to derive equations for each particular case.

Mr. Turner's Equations (1) and (2), with the interpretation given by him, are not "the fundamental equations of extensional stress and strain established a generation ago and accepted by Grashof and all authorities on the subject, since then".

In the first place, the general equations to which Mr. Turner refers are three, and not two, namely:

$$\left.\begin{aligned} E\,e_1 &= p_1 - K\,p_2 \\ E\,e_2 &= p_2 - K\,p_1 \\ E\,e_3 &= -\,(p_1 + p_2)K \end{aligned}\right\} \qquad \ldots\ldots\ldots\ldots\ldots\ldots (34)$$

They are obtained by considering the equilibrium of a small cube (element), two faces of which are always normal to the vertical plane of symmetry of the cross-section of a beam, and, at the same time, are parallel to one of the two "principal stresses" reacting at that point;

Mr. Janni.

it follows that the other two faces of the cube, will be parallel to the other "principal stresses".

Let A-B (Fig. 22) be the vertical profile of a cross-section of a beam, and O the position (altitude) of its neutral axis.

The position of the elemental cube at this point is shown, as well as the directions of the "principal stresses"* acting on that cube at that point. (If p_1 is assumed to be negative, then p_2 is positive, and *vice versa*.)

It being known that the directions and values of the principal stresses, changeable with the altitude of the point of the cross-section at which we consider the cube, it follows that only at the top and bottom of the section this cube has two faces horizontal, and that it revolves through 45° in passing from O to A, and through an additional 45° in passing from O to B.

Furthermore, it is known that the third equation of this system, which refers to the cross deformation of the elemental cube, is zero only when these equations are applied to the cubical element at the neutral axis of the beam, because then, and only then, $p_1 = -p_2$, or $-p_1 = p_2$. Mr. Turner can easily verify this by examining the circular diagram theory, as written by K. Culmann.†

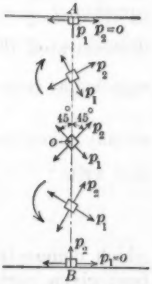

FIG. 22.

Mr. Turner's attention is called to the fact that these stresses, p_1 and p_2, lie on a vertical plane normal to the cross-section of the beam, and not on a horizontal plane, as he states, which is quite different. He will notice, also, by inspecting Fig. 22, that these stresses cannot be made zero where and when he pleases; they are zero only when the circular diagrams, previously mentioned, make them so. These equations, therefore, with the correct interpretations, as given by the writer, are to be regarded as the general equations of equilibrium of a beam, and, as such, they are accepted, of course, by everybody.

Neither Grashof nor any other authority would have accepted the equations, as given and interpreted by Mr. Turner, as general equations for the deflection of a beam, and the use of his illustrious name in this connection is not altogether commendable.

There is also another remark to be made regarding the interpretation of the general equations of the equilibrium of a beam. The writer notes that Mr. Turner applies these "would-be" general equations for this case of equilibrium to a plate, by simply changing the word "beam" to "plate", without thinking that theory cannot be made to apply by simply substituting one word for another. There is great static difference between the equilibrium of a plain beam and a plate.

* These "principal stresses" are sometimes designated improperly "diagonal stresses".

† "Die graphische Statik." Zurich, 1866–75.

Mr. Janni.

Equations (1) and (2), as given by Mr. Turner, are simply Equations (26) and (27), as given by the writer; that is, the equations of equilibrium (not general) applied to the particular case under discussion, as has been shown already in this closing discussion, with the additional difference that the elemental cube, in this case, is assumed to have always two faces horizontal, no matter at what altitude it is considered. So that, when Mr. Turner says: "if p_2 is zero, as it would be in a beam", he is quite wrong. As a matter of fact, in an ordinary beam (and Mr. Turner discusses this kind of beam) the value of his p_2 is never zero, except at the plane of the neutral axis.

The fact that it is never zero in an ordinary beam, though in the ideal beam, as chosen by the writer, it is logically constantly zero, constitutes the radical difference between the two cases of deflection (common beam and ideal beam).

In considering his case of a plate, Mr. Turner states:

"Assuming that K (Poisson's ratio) is zero, it has been demonstrated that the work done in a circular direction is equal to that done in a radial direction. Now, radial deformations alone determine the vertical position of the cantilever plate, and though the circumferential deformations necessarily accompany radial deformations, they provide a means of storage of energy which is not involved in nor determines the vertical deflection".

In the first place, the coefficient, K, of Poisson is far from being zero, therefore, the resulting demonstration, to which he refers, may be interesting, but its conclusion is untrue.

In the second place, does Mr. Turner really mean what he says about the storing of energy? Does he really mean to say that in the theory of elasticity it is quite possible to have work without the corresponding displacement? In other words, if the writer understands rightly, the expression for the work, going entirely by definition, is given by $L = F \times \delta$, in which L is the work, F is the applied force, and δ is the elastic displacement, Mr. Turner states that, by assuming $\delta = 0$ the quantity, L, is not zero. The writer prefers to believe that Mr. Turner did not mean that; although he said so repeatedly, in different ways.

He says, furthermore: "Now, the relative stiffness of the continuous and simple beam, is known by theory to be as five to one". This statement is not exact; the ratio between the deflections referred to is correct only in the case of a beam rigidly supported at its ends, and one freely supported. In dealing with a continuous and a simple beam, the ratio given by Mr. Turner is not exact, but varies according to the hypothesis of loading of the spans.

Apart from this inexactness in Mr. Turner's statement, however, we can see by the statement itself that he makes comparison with a beam with fixed ends, when it is known that such cases of equilibrium

Mr. Janni.

are discarded from reinforced concrete design; neither does he state whether, in his "numerous experimental results", he used the partial or total loading.

The writer must confess that he is unable to follow Mr. Turner in his "photographic" conception. It may be, however, that his copper half-tone plate comparison may be very interesting to the reader who knows something of this subject; the writer can see neither the plate nor the screen.

At this point of his discussion, Mr. Turner enters another field: "shearing rigidity and flange rigidity". Judging from his nomenclature for this particular internal stress, it seems that he makes a difference between shearing rigidity and what he terms "flange rigidity". It is difficult for the writer to understand, from this new phrase, "flange rigidity", whether Mr. Turner means the resistance of the flange to shear, or some other internal stress just discovered. However, if he agrees with the writer that, usually, exclusive of compression (tension) and shear in the deflection of a beam, there is no other internal stress to be considered, then the writer will conclude that this "flange rigidity" is nothing but the resistance of the flange to shear.

This being the case—as it must be, according to the elementary principles of theory—the shearing rigidity and flange rigidity are simply plain shear in both cases, and therefore all theorems concerning shear may be applied.

Mr. Turner says:

"Another matter which is very puzzling to many is the fact that the mechanics of a solid is such that ordinary rules of statics do not apply, that is, the rules of statics as applied to the separate members of framed structures are not here applicable."

As an example of this he states that, "under pure statics, a force in one direction cannot affect the magnitude of the force at right angles thereto", but in mechanics "that is not the case", since here the "deformation in one direction under a given force affects and influences the deformation produced by a force at right angles thereto". This—to say the least—shows a peculiar confusion between forces and deformations, as well as a quite new conception of statics.

In the first place, all the rules of statics, being mathematically true, stand, no matter whether they are applied to a separate member or to a framed structure; there is not, and never will be, it can be stated with mathematical certainty, a single problem in mechanics where these rules will not apply, as Mr. Turner wrongly states.

It is true that sometimes the rules of statics are not sufficient for the solution of certain problems, for instance, the elastic arch, the continuous girder, etc., and then help must be obtained outside of

statics; but this does not mean that these rules do not apply. It is no wonder, therefore, that many are very much puzzled by such a statement as Mr. Turner has made. Mr. Janni.

Secondarily, though the example he cites as a proof of his assertion does not mean anything bearing on the assertion itself, it shows an alarming confusion in Mr. Turner's mind between deformations produced by force and by components of that force; between causes and effects.

The deformation produced by the forces, p_1 (Fig. 14), affects that produced by the forces, p_2, but this does not mean that the forces, p_1, are the components of the forces, p_2, or *vice versa*. The forces, p_1, have no partial or total components along the forces, p_2, and this is true here as well as in plain statics; the same may be said of p_2 with respect to p_1.

From the foregoing statement of Mr. Turner, it can be safely said that, to the realization of perpetual motion, is a very short step.

Taking up the matter of distribution of shearing stress, both in a beam and in a slab, Mr. Turner says:

"In the beam horizontal shearing stresses act only in horizontal planes, but in the slab, with its double change in curvature, horizontal shearing forces act in vertical planes as well."

Apart from the fact that the double change in curvature of the slab has nothing to do with the distribution of this internal stress, it may be said that the foregoing statement is altogether wrong. Mr. Turner undoubtedly knows that at any point of the cross-section of a beam there is a horizontal shear and a vertical shear, and these two stresses are equal, this conception being very elementary. How, therefore, can he say that in a beam there is no vertical shear? If he, reversing the entire theory on shear, does not admit this vertical shear, he does not know that without it the internal stresses, taken altogether, cannot be in equilibrium.

Concerning the slab, however, he concedes that there is a vertical shear, but that vertical shear is there on account of double change in curvature. That is equivalent to saying that, if the slab has no double curvature or has more than a double curvature, the vertical shear will disappear.

Whatever Mr. Turner's ideas are regarding this matter of shear, it may be stated that, as a matter of fact, the vertical shear in the slab is always there when there is horizontal shear. In other words, the law of the distribution of shearing stresses, along the horizontal and vertical faces of the elements of a beam, holds good also in a slab, as it must.

It is true that in a square slab, for instance, there are lines along which there is no vertical shearing stress, but, accordingly, along those

Mr. Janni. same lines there is no horizontal shear either; of course, this happens when the slab is assumed to be uniformly loaded.

Mr. Turner, the writer is sure, must know that the theory of shear, holds good for beams, or for slabs, or for arches. This theory is quite independent of the external shape of the solid. The only assumption—made at the beginning—is that the two cross-sections, A-B and A'-B' (Fig. 23), of a solid shall be so near that, even if the whole solid has variable shape, these two sections may legitimately be considered as equal.

The single or double curvature mentioned by Mr. Turner is a deformation brought about by the application to the solid of external forces, and, as such, like all elastic deformations, they have no influence whatsoever on the law of the distribution of the internal stresses of the solid.

Sometimes these deformations, as in the case of arches, bring out additional stresses which are to be added properly to the former ones; but this does not destroy, nor modify in the least, the manner in which the former ones are distributed in the interior of the solid. Therefore, speaking of double curvature of a solid as affecting the law of distribution of internal stresses is erroneous.

From Mr. Turner's remarks concerning the two glued or bolted planks and the cured concrete slab, it appears that he considers all the strength of a beam and of a slab to depend on the shearing stress at the neutral plane of these solids.

FIG. 23.

As a matter of fact, the shear at the neutral plane (as well as that at any other plane) is necessary to the resistance of these solids, but is not more necessary than tension and compression. All these internal stresses have their rôle; all are necessary, but one is not more necessary than the other. Take the case of the two planks; after they are bolted together it is found (correctly) that the resistance of this new beam is twofold, and from this fact Mr. Turner concludes that this is due to the shear obtained along the neutral plane; accordingly, he speaks of its great importance in the resisting quality of the beam. He, however, does not stop to think that, if this new beam is cut across vertically (for instance, at its center) from the bottom up to the glued plane, or is cut with a V-shaped notch from the top down to the glued plane, it, with all its shearing rigidity, is worth no more than one of the planks of which it is constructed, as far as bending is concerned. Is there any reason, therefore, for giving to the shear rigidity so much preference?

The writer has taken up simply the important theoretical points brought up by Mr. Turner, but has not discussed either his criticism of the paper, or his eulogy on a certain theory on flat slabs written by Mr. Eddy.

Mr. Janni.

As Mr. Turner has not shown any particular care in his quotations from theory, and has not been clear in his conceptions of the strength of materials, the writer is of the opinion that his criticism of the paper has no bearing whatever.

Therefore, if the "most gratifying concordance between deflections and stresses", as Mr. Turner states, has been found on the strength of the kind of theory quoted by Mr. Turner in his discussion, is there any "more cogent reason" for stating that the theory he is supporting is not a theory but merely ordinary guesswork, and as such should be objectionable, for it is unsafe?

Will engineers dump and bury forever a public patrimony, called theory, in order that Mr. Eddy's theory may stand up?

No one will have any hesitation in his choice.

In reply to Mr. Mensch's remark, that the writer's theory is misleading because the moments calculated by it are not the same for all strips, the writer wishes to state that he never meant that the reinforcement in the entire slab should be computed according to those values. It is stated in the paper that the intention is to calculate the maximum in each direction only, and for this reason alone he selected the middle strips.

Knowing the maximum values of the moments at the center of the middle span of each middle beam, and their values at the support points, the arrangement of the reinforcement is an easy matter.

Since the remaining part of Mr. Mensch's discussion, like a good part of several of the others, seems to be a discussion of Mr. Jonson's remarks, to which the writer already has answered at length, it is thought expedient to disregard that part in order not to present, practically, the same arguments.

Mr. Marsh brings out the fact that Equation (12), for ratios of $\frac{l_1}{l}$ greater than $\frac{5}{3}$, gives a transverse coefficient greater than unity and a minus quantity for the longitudinal coefficient. This he points out as a defect of this formula.

Several formulas in engineering mathematics, as Mr. Marsh undoubtedly knows, need logical interpretation before proceeding to apply them.

Take, for instance, the very formula in which the coefficient of Poisson has its origin, that is:

$$\left(1 + 2\,\frac{e}{m} - e\right) A \,.\, \Delta x = V'$$

where: e = stretching of the fiber per unit of length;
m = coefficient of Poisson;
A = area of the cross-section of the fiber;
Δx = its length;
and V' = volume of the stretched fiber.

Mr. Janni.

In order to obtain our result, we must observe first that the volume of the stretched element cannot, logically, be increased by the actions of the two tensile forces applied to it; accordingly, we are able to put the condition that $\frac{e}{m} < \frac{1}{2} e$, from which we derive that the value of $\frac{1}{m}$ is between 0 and $\frac{1}{2}$. Without this logical assumption, we would never be able to determine the limits of $\frac{1}{m}$. Indeed, we might come to the absurd conclusion that the volume of the fiber, $A \cdot \Delta x = V$, increases under the action of extensional forces.

The formula of Euler is another instance. Mr. Marsh undoubtedly knows that the indiscriminate use of this formula may lead to absurdity, due to its nature, as it is not a purely mathematical formula but one of elasticity.

A formula of elasticity is to be regarded as absurd when at each and every stage of its values it brings out absurd results, or else it is derived on absurd assumptions.*

The writer, however, is indebted to Mr. Marsh for having pointed out this fact, as it has thus given an opportunity to explain fully this point also.

Mr. Marsh remarks also that the introduction of Poisson's ratio is doubtless essential to this problem, but he has misgivings regarding its practical utility and accuracy.

It can be pointed out that the little justified doubt concerning the accuracy of the coefficient of Poisson does not destroy the correctness of its introduction in this problem. There is an incontestable physical phenomenon, which happens in this case of deflection, and as this was recognized as essential by the writer and also by Mr. Marsh, it must be taken into account.

The omission of the coefficient of Poisson in any flat slab theory, means the undermining of that theory.

The writer regrets that Mr. McMillan has devoted his valuable time entirely to the discussion of the points brought out by Mr. Jonson. It is true that if those points had cast a new light on the whole theory of reinforced concrete they would have undermined also the solution of the problem proposed and solved by the writer, but Mr. McMillan knows very well that those points were not new by any means, and that their solution was already a matter of fact, and this apart from the fact that the solution proposed by Mr. Jonson lacks any serious mathematical support, as has been shown.

* In pure mathematics we have a similar state of affairs in the solution of equations above the first degree. Mathematically speaking, all the roots of an equation are true and solve the same equation; but how many of those roots must we discard because they lead to absurd conclusions in our problem? Does this mean that the theory of the solution of equations is wrong?

Mr. Janni.

As a general impression of the various discussions on this paper, it can be said that only those by Mr. Goodrich, and by Mr. Godfrey took up the important point brought forth by this problem, namely, the great variation of the moments in a continuous slab determined by the yielding of the supports.

It seems to the writer that attention has been centered only on the formulas for the design of a flat slab rigidly supported, which formulas, after all, were purely incidental to the problem.

Apart from the fact that these formulas, as far as the difficulty of the problem has allowed, have been demonstrated to be correct both in their conception and from a mathematical point of view, there is the fact that, even applying other formulas, theory would have given the same results, as far as difference of moments in both hypotheses is concerned.

The writer, whose professional activity is not narrowed down to the designing of reinforced concrete flat slabs, was unaware that there could be such a thing as "A flat slab specialist", but, after this discussion, he must say that, if there is such a specialty, its theory needs some decided improvement.

In this closure the writer cannot refrain from expressing his opinion concerning technical discussions.

There is no doubt that a discussion on a scientific question is more apt to bring to light important truths than an ordinary publication on that subject, and, in the opinion of the writer, a sound, well-thought-out contribution to the subject in question is not only welcomed by the interested public, but more so by the author of the paper himself. Remarks and opinions on a technical problem have a bearing upon it, if they are supported either by theory or by logic, but when they are, so to speak, supported only by a sadly crippled or misunderstood theory, such discussions then become useless and somewhat ridiculous.

Paper No. 1375

THE PRESERVATION OF SANDY BEACHES IN THE VICINITY OF NEW YORK CITY*

By Elliott J. Dent, M. Am. Soc. C. E.

With Discussion by Messrs. Lewis M. Haupt, Charles H. Higgins, Allen Hoar, F. William Schwiers, A. W. Buel, B. F. Cresson, Jr., and Elliott J. Dent.

Synopsis.

The object of this paper is to set before the Society the result of the writer's study of the effect of wave action on the sandy beaches skirting the south shore of Long Island and the New Jersey shore north of Asbury Park, to call attention to the means by which improved beach property may be protected, and to emphasize the damage that must inevitably result to the beaches as a whole if the erection of structures that interfere with littoral drift is allowed to continue.

The paper treats of such subjects, only, as are considered of primary importance in the particular locality under consideration. It is subdivided into sections, and the contents and conclusions are described by sections:

Tidal Currents and Ocean Currents.—These currents are of no effect except in the vicinity of inlets, and receive only brief mention.

Waves.—The behavior of deep-sea and shallow-water waves prior to the plunge receives a brief mention. The phenomena accompanying

* Presented at the meeting of June 7th, 1916.

the plunge, the up-rush and the back-wash of the wave, and the phenomena accompanying the undertow are discussed and illustrated in some detail.

The Origin of Beach Sand and Gravel.—A brief discussion is given, and the conclusion is reached that the principal source of such material is not the grinding up of cliffs, etc., but the sorting out of particular sizes from the soil formed by the decomposition of the primary rocks.

Typical Beach Forms.—Typical beach forms are discussed and illustrated, particular emphasis being placed on the distinction between the temporary berms and the more permanent dunes, etc.

Constructive and Destructive Power of Waves.—The transporting power of the up-rush, back-wash, and undertow are discussed. The conclusions are arrived at that wave action always causes a transfer of material from the beaches to deep water, that in the normal case berms are constructed during stormy weather and eroded by undermining during quiet weather.

Littoral Drift, and Jetties and Groins.—Littoral drift is described, and the effect thereon of inlets, jetties, and groins is discussed. The conclusions are reached that, for beaches such as those under consideration, inlets, jetties, and groins interfere with littoral drift and increase the quantity of material permanently lost to the beaches.

Bulkheads.—The proper functions of bulkheads and sea walls, their proper location with respect to the berms, and the absence of extensive erosion due to back-wash, are discussed. The conclusions are reached that such structures, when their strength is commensurate with their exposure, will afford a real protection to lands in their rear, that their existence will not prevent the formation of berms when other conditions are favorable, that if not placed too far seaward they will not interfere with littoral drift, and that when used to extend the uplands beyond their natural limits such structures may cause a serious loss to the beaches to their leeward.

The increasing value of ocean beach property has led many investors to build nearer and nearer the shore line, relying on the erection of shore-protection works to guard their investments against damage from the sea. Under-estimates of the forces to be resisted and over-

estimates of the efficacy of certain types of shore-protection works have resulted in extensive property losses in the immediate vicinity of New York City. In view of the importance of such beach colonies as Coney Island, the Rockaways, and Long Beach, on the south shore of Long Island, and in view of the existence of similar colonies extending in a nearly continuous line along the New Jersey coast from Seabright to beyond Asbury Park, the writer has been tempted to prepare this paper, setting forth such of the general principles of beach formation and erosion as apply to these localities.

The first time he was required to report on plans for the protection of a portion of one of these beaches, he advocated the erection of a system of groins. The direction of the littoral drift was well established, and, in the literature on the subject, no doubt was expressed as to the efficacy of such structures "when properly designed". The case in point appeared to be so simple that the writer had no doubt as to his ability to design the structures properly.

Subsequently, the writer spent much of his time for two summers walking the beaches around New York City. Occasional beach trips were made during the winter, and certain beaches around San Juan, Porto Rico, with which the writer was familiar, were re-visited during the summers of 1914 and 1915. At the same time the literature on the subject was quite thoroughly examined. Memoranda made during these visits furnished the foundation of observed facts on which the discussion herein presented has been based.

There are certain general principles of wave and current action that apply to all beaches, but in one instance the controlling force may be very different from that in another. An effort will be made to state quite fully the principles in regard to the major forces at work on the sandy beaches around the entrance to New York Harbor. Some of the forces emphasized in this paper may be of little or no importance in some other particular locality; and phenomena which, in that other locality, may be of controlling importance may be entirely ignored in this paper. As an illustration, it may be stated that the problem of shore protection at the foot of the caving bluffs along the north shore of Long Island is totally different from that to be faced along the sandy beaches of the south shore; the latter is discussed in this paper.

Tidal Currents.

On an open coast, far away from any inlet, there is a semi-daily landward and a semi-daily seaward current. If the tide is rising at the rate of 1 ft. per hour, and if the mean depth is 1 ft. at a point 3 600 ft. off shore, there will be a shoreward current at that point having a mean velocity of 1 ft. per sec. As the slope of the foreshore, in the locality under consideration, is much greater than 1 in 3 600, the subject of currents due to the flood and ebb tides may be dismissed, except in the vicinity of inlets.

Ocean Currents.

The Gulf Stream directly east of the mouth of Chesapeake Bay has a surface velocity of about 2½ ft. per sec. If a steady current of equal velocity flowed along the New Jersey coast, in shallow water, with a loose sandy bottom, we might expect to find sand waves, deep pools, and shallow bars, all subject to frequent changes in position. Such conditions do not exist along the shores under consideration, and, so far as this paper is concerned, no discussion of ocean currents is necessary.

Waves.

Wave action is an important factor in the construction or destruction of ocean beaches. A few of the general principles will be given here, and the reader may consult the various works on the subject if further information is desired. The writer has followed the paper "Wave Action in Relation to Engineering Structures".*

The form of a wave is normally that of a common or prolate cycloid. If we assume several filaments of water, parallel to the direction of travel of the wave, and at certain selected distances below the surface of the water, we shall find that there is no tendency of these filaments to cross as the wave passes by. The passage of a wave does not mix the surface water with the deeper water, or *vice versa*.

In deep water each particle of water coming within the influence of a wave moves in circular orbit. (Fig. 1.) The orbital velocity is uniform, and in the upper half of the orbit the motion is in the

* By the late Col. D. D. Gaillard, Corps of Engineers, U. S. Army, published as Professional Paper No. 31, Corps of Engineers, U. S. Army.

direction of wave travel. When the wave has passed, each particle is left in the position it occupied before the wave arrived. The radii of the orbits decrease with increases of depth below the surface.

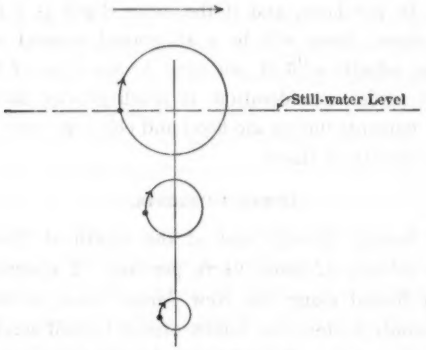

FIG. 1.—AS A DEEP-WATER WAVE PASSES, EACH PARTICLE OF WATER MOVES IN A CIRCULAR ORBIT; THE RADII OF THE ORBITS DECREASE WITH INCREASED DEPTH BELOW THE SURFACE; WHEN THE WAVE HAS PASSED, EACH PARTICLE IS LEFT IN ITS ORIGINAL POSITION.

In shallow water (Fig. 2) the orbits are elliptical in form. The semi-axes of the orbits decrease with increases in depth below the surface, but the focal distance of all orbits is constant. The horizontal or major semi-axis approaches one-half of the focal distance as a limit. The vertical or minor semi-axis approaches zero as a limit. A particle of water very near the bottom moves in what is, to all intents and purposes, a straight line. It is important to note the orbital velocity of such particles.

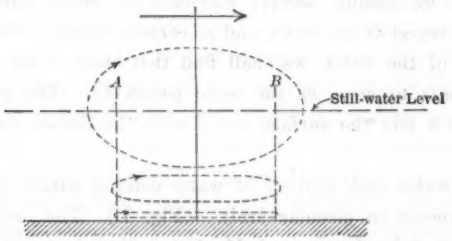

FIG. 2.—IN A SHALLOW-WATER WAVE, THE ORBITS OF THE VARIOUS PARTICLES OF WATER ARE ELLIPSES; THE FOCAL LENGTH OF ALL ORBITS IS A CONSTANT, *A B*; NEAR THE BOTTOM THE ORBITS APPROACH A STRAIGHT LINE AS A LIMIT; THE VELOCITIES ACCOMPANYING THE FORWARD AND BACKWARD SWINGS ARE EQUAL.

If a circle is described, concentric with the elliptical orbit, and with a diameter equal to the major axis of the orbit; if a point moves along the circumference of the circle with a uniform velocity, such that the time required to complete the circle is the same as that required by the particle of water to complete its orbit, then the orbital velocity of the particle of water will be such that it will at all times lie vertically above or below the point on the circumference of the circle.

The orbital velocity of the particle of water is at a maximum as the trough or the crest of the wave passes over it. As the trough passes, the orbital motion is opposite in direction to the travel of the wave; as the crest passes, the orbital direction is with the wave travel. The velocities in the direction of wave travel and in the opposite direction are equal.

With a moderately sloping foreshore, deep sea waves approaching the beach are diverted in direction. The tendency is to change direction until the travel is perpendicular to the beach. Waves seldom strike the beaches under consideration at an angle of 45° from the perpendicular, or greater.

Assume for the moment that one is observing the effect of a heavy swell following a storm. In deep water a large rounded wave would be seen, its surface section corresponding approximately to the curve of a prolate cycloid; as the water becomes more shallow, the wave rises higher, becomes more pointed, and the section corresponds more closely to that of a common cycloid. When a certain depth is reached, the wave breaks and the upper point falls over, striking the front slope. Depending on the character of the bottom, the magnitude of the wave, etc., this first break may occur in depths exceeding 20 ft.

After the first break, a new wave is formed and travels shoreward until it in turn breaks when it reaches a certain depth. This process continues until water only a few feet in depth is reached, and then the wave breaks for the last time. (Fig. 3.)

This final break is called the plunge, and the point at which it occurs is called the plunge-point.* When the plunge takes place, orbital motion ceases, and a boiling, foaming, sheet of water rushes

* The terms "plunge", "up-rush", and "back-wash" are borrowed from "Coast Erosion and Foreshore Protection", by John S. Owens and Gerald O. Case, Assoc. M. Am. Soc. C. E.

up the beach. This will be referred to as the up-rush. As the wave flows up the beach, the boiling diminishes until a relatively quiet sheet of water has been formed. When the kinetic energy has been entirely wasted, or transformed into potential energy, due to the increase in elevation, the back-wash begins, and the water flows down the slope in a smooth sheet. The velocity during this back-wash constantly increases, and, except for a few feet near the upper margin, the back-wash has, in sand, a considerable transporting power.

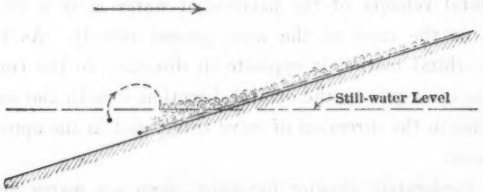

FIG. 3.—WHEN THE PLUNGE OCCURS, ORBITAL MOTION CEASES, AND A BOILING MASS OF WATER RUSHES UP THE BEACH; WHEN THE KINETIC ENERGY HAS BEEN ENTIRELY DISSIPATED, OR TRANSFORMED, THE BACK-WASH BEGINS, AND THE WATER FLOWS DOWN THE SLOPE IN A SMOOTH SHEET; THE TRANSPORTING POWER OF THE UP-RUSH ON THE UP GRADE MUST, FOR EQUILIBRIUM, BE EQUAL TO THE TRANSPORTING POWER OF THE BACK-WASH ON THE DOWN GRADE.

On sandy beaches, the height of the wave at the time it reaches the plunge-point is not great. A height of 5 ft. is not infrequent, but the writer does not recall having seen breakers as high as 8 ft. The depth of water corresponding to the plunge is seldom more than 3 ft.

An after-effect of the plunge that requires special notice is the undertow. When the back-wash reaches a certain point, normally about the line of the still-water level, a new wave is encountered. The water from the earlier wave must find some escape to sea, and it is a matter of common knowledge that an off-shore current, hugging the bottom, is formed. This current is known as the undertow.

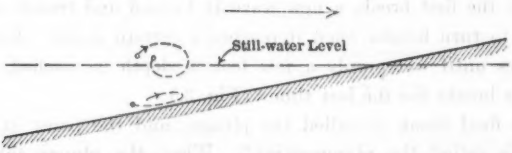

FIG. 4.—NEAR THE SHORE, AS A RESULT OF THE UNDERTOW, THE CLOSED ORBITS ARE REPLACED BY SPIRALS; NEAR THE SURFACE, THERE IS A PROGRESSIVE LANDWARD MOVEMENT, AND NEAR THE BOTTOM THERE IS A SEAWARD MOVEMENT.

Where the undertow exists, therefore, there must be a new condition of wave action, as shown by Fig. 4. Instead of moving in

closed orbits, the particles of water move in spirals. Near the surface there is a progressive movement shoreward, and near the bottom there is a corresponding movement seaward. If, where there is a good surf running, a bather will raise his feet from the bottom and float on the surface, he will almost invariably drift toward the beach. If he is standing on the bottom, the nearly constant pressure of the undertow will frequently outweigh the occasional thrust of the wave and a considerable effort may be necessary to avoid being carried seaward. The undertow normally concentrates into streams of considerable velocity, and in such places the lower spiral of Fig. 4 is replaced by a current of varying velocity, but always flowing seaward.

The foregoing discussion of waves has been somewhat idealized. Waves ordinarily approach the shore from a diagonal direction, and the undertow leaves the beach by a diagonal on the opposite side of the normal. The undertow may concentrate into a stream nearly parallel to the beach and break out to sea at intervals. Such phenomena will be observed by any one making a study of a particular beach, and it will readily be understood that they are modifications of the idealized case.

The Origin of Beach Sand and Gravel.

The grinding away of rocky headlands and the accompanying reduction of ledge rock to gravel and sand is frequently referred to in print. Similarly, the wearing away of boulders as they are carried along by mountain torrents is a constantly recurring theme, attractive to the imagination. If, however, the prosaic engineer will pause for a moment to consider, it will be apparent that these are relatively unimportant sources from which beach sand is derived.

The constant agitation of a gravel beach must inevitably wear away the stones and gradually reduce their size. The rounded form of the pebbles is due to this wearing process. Each pebble is constantly reduced in diameter by the conversion of its outer skin into dust, but, by the time any given quantity of gravel can, by the attrition process, be reduced to grains of sand, there will remain only a small percentage of the original volume.

The principal source of sand in America is the verdure-covered mountain, hill, and valley. Wherever rain falls and vegetation grows the primary rocks are undergoing a process of disintegration. Certain

components are carried away in solution, other constituents are transformed into clay, and the quartz crystals remain nearly unchanged. Let some of this decomposed rock, which is called soil, fall into a stream of running water, and the various sizes are quickly sorted out. The clay may be carried to deep water in the ocean without a halt, the finest sand may travel hundreds of miles before it is temporarily deposited, the coarser sand may be deposited within a few miles, and some fragments of rock may be rolled only a few feet during each freshet, and may, in traveling a few miles, be converted into typical rounded pebbles.

The nature of the sand found in most rivers and on most beaches is proof of its origin. It is the friable but insoluble quartz which has survived, and the grains are much more angular in form than pebbles formed by the attrition process. In the immediate vicinity of rocky cliffs, exceptions may be noted, and the writer has seen large areas covered with volcanic sand, but the beaches to which this paper particularly refers are no exceptions to the general rule.

Typical Beach Forms.

If all except wave action could be eliminated, the normal form of beach would be a series of berms. Several such berms are sometimes found in the case of gravel beaches. In the case of sand beaches, two berms are often noticeable.

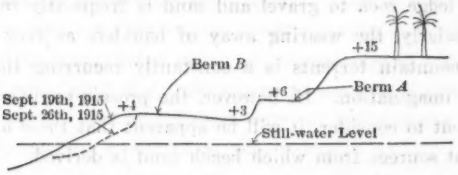

Fig. 5.—Beach at San Juan, Porto Rico, September, 1915. The Cocoanut Grove Stands on Semi-Permanent Sand Dunes; Berm *A* Represents the Remains of a Much Wider Berm Built up During the Preceding Winter and Eroded Back to the Scarp During the Summer; Berm *B* was Formed During a Storm, about September 15th, 1915.

Fig. 5 shows the general character of a beach at San Juan, Porto Rico, as noted on September 19th and 26th, 1915. This beach builds up every winter during the stormy season. During the summer or quiet season, it cuts away, the limit of cutting being indicated by the location of the cocoanut grove. Berm *A*, at Elevation + 6, was formed during the winter of 1914-15. By September, 1915, the beach had cut away as far as the upper scarp which, in September,

1915, marked the limit of that berm. During a 3-day storm, about the middle of September, a new berm, *B*, was built up in front of Berm *A*, and at a lower level. During relatively quiet weather prevailing from September 19th to 26th, the lower berm was eroded by undermining, as indicated by the broken line. The high bank on which the cocoanut grove stands represents a relatively permanent formation; the lower berms are temporary in character. Almost identical conditions have been observed at Long Beach, Long Island, on numerous occasions, and on one occasion four berms were noted in a gravel beach at Mattituck, Long Island.

Information as to the form of beaches below the low-water line is not as complete as could be desired. In general, there is some depth at which the beach quite suddenly assumes a much flatter slope than it has at and above the level of mean tide. Around New York City, with a mean tidal range of about 4.5 ft., this change appears to come at about the level of mean low water. At San Juan, Porto Rico, where the tidal range is about 1.1 ft., the change of slope is very sharp, and occurs in water from 2 to 3 ft. deep. A beach noted by the writer on the Island of St. Thomas was similar to that at San Juan.

Constructive and Destructive Power of Waves.

Just before the plunge, a wave, by virtue of the orbital velocities of its component parts, possesses a considerable store of energy. After the plunge, this energy is largely dissipated, due to the turbulent flow accompanying the up-rush. To preserve the equilibrium of the beach, the turbulent up-rush must have a sand-carrying capacity on the up-grade equal to that of the back-wash on the down-grade. Shoreward of the plunge-point, the constructive power of the up-rush is greater than the destructive power of the back-wash and undertow. The slope of the beach, taken in connection with the character of the beach material, is an indication of the extent of this difference. It would seem that, seaward of the plunge-point, the destructive agencies are more powerful than the constructive agencies. Referring to Fig. 4, it is seen that, near the bottom, the resultant movement is seaward. Unless the sand can be carried to the top of the wave, there is no force to carry it shoreward. The ultimate effect of wave action, therefore, is a constant transfer of sand from the beach to deep water in the ocean.

As already stated, there is, in the beaches near New York City, a change in slope near the line of mean low water. Above that line, the slope is the measure of the difference in transporting power, for the particular material under consideration, of the up-rush and the back-wash of the wave. In coarse sand at San Juan and at Seabright, N. J., this slope averages perhaps 1:12; at Long Beach, N. Y., with fine sand, the slope is perhaps 1:40. For any locality, this slope is nearly constant, regardless of the magnitude of the waves that have created it and regardless of whether it is the result of an addition to, or a denudation of, the beach. Seaward of the foot of this slope, the inclination of the bottom is much less.

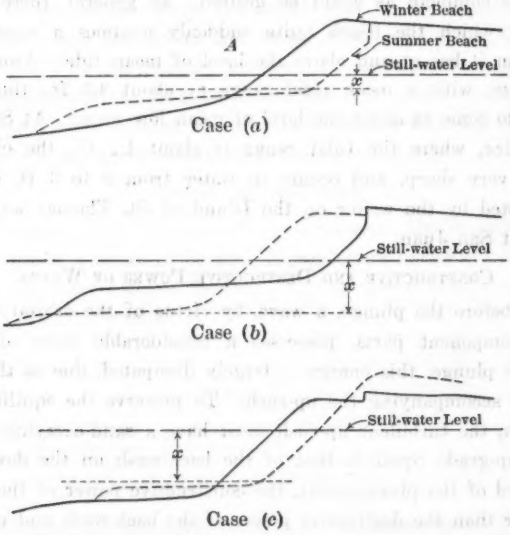

FIG. 6.—THE DEPTH OF WATER AT THE PLUNGE POINT IS INDICATED BY THE DIMENSION, x; THE FORM OF THE BEACH BEFORE IT IS ATTACKED BY WAVES PLUNGING AT THE DEPTH, x, IS SHOWN BY THE FULL LINE, AND THE NEW FORM ASSUMED IS SHOWN BY THE BROKEN LINE.

CASE (*a*) ILLUSTRATES THE EROSION OF A BEACH BY WAVES OF LESS MAGNITUDE THAN THOSE BY WHICH THE BEACH WAS BUILT UP.

CASE (*b*) ILLUSTRATES THE UPBUILDING OF A BERM BY HEAVY WAVES WHEN THE STILL-WATER LEVEL IS AT ITS NORMAL ELEVATION.

CASE (*c*) ILLUSTRATES THE RE-ADJUSTMENT OF THE BEACH FORMED IN CASE (*b*) WHEN ATTACKED BY WAVES OF THE SAME MAGNITUDE AS THOSE ASSUMED IN CASE (*b*), BUT STRIKING THE BEACH AT A TIME WHEN THE STILL-WATER LEVEL IS ABNORMALLY RAISED.

An explanation of the observed fact that berms, built up during stormy seasons, are eroded by the less violent wave action of the calmer

seasons, and that berms attacked by storm waves may be either built up or eroded according to circumstances, may be obtained from Fig. 6, in which three typical cases are indicated.

Case (*a*) represents conditions such as exist when the winter berms are attacked by the summer waves. The plunge-point is at some depth, *x*, and this is the point of maximum disturbance. Shoreward of the plunge-point, the waves maintain a nearly fixed slope, as described in the first paragraph on page 1796. Seaward of that point, the slope of the bottom is steeper than required for equilibrium. The result is a transfer of sand from the berm to the under-water section, and the summer beach indicated by the broken line is formed.

If now, Case (*b*), waves of greater magnitude attack the summer beach of Case (*a*), the plunge-point, in the average case, will be moved seaward to water of some depth, *x*. Shoreward of the plunge-point the slope of the beach is flatter than required for equilibrium, and a transfer of sand toward the beach commences. The ultimate result is a new berm such as shown by the broken line. It should also be noted that at the plunge-point there is also a transfer of sand seaward, and, as this sand is carried into deeper water than that where it lay in the summer beach, the probability of its eventual return to the beach has been diminished. In other words, though the berm has been rebuilt, a certain quantity of beach material has been wasted in the process.

In Case (*c*) it is assumed that the beach formed under Case (*b*) is, in turn, attacked by waves plunging in water of the same depth as in Case (*b*), but that the attendant circumstances are such that the still-water level has been raised. Under these conditions, the berm will be built to a higher level, but the sand used in this elevating process is taken from the face of the berm itself, and the width of the berm is correspondingly decreased.

Many other conditions might be assumed and discussed, but those chosen will show why the beaches around New York City, throughout the summer, present to the eye of a visitor a scarp indicative of erosion; they will show why, in many cases, if not in the majority, the berm at the beginning of the summer is wider than it was at the close of the preceding summer; they will also show why the maximum damage to beach structures usually occurs during an extraordinarily high tide.

The foregoing refinements might have been omitted, and the writer might have limited himself to a brief statement to the effect that, above a certain hydrographic contour, the waves exercise a powerful scouring effect on the bottom; that the sand composing the bottom is constantly agitated and can find no rest until it has reached deep water, or until it has been cast on the beach above high-water mark; that the greater the magnitude of the waves, the wider the zone of agitation, the higher the beach to which part of the material escapes, and the greater the depth to which other material is carried.

Along the south shore of Long Island, the waves, for the greater part of the year, beat on the shore from a direction slightly east of the normal to the shore line. This shore is protected from the northerly storms, and, if the northerly winds are eliminated, the remaining storms will come mainly from an easterly direction.

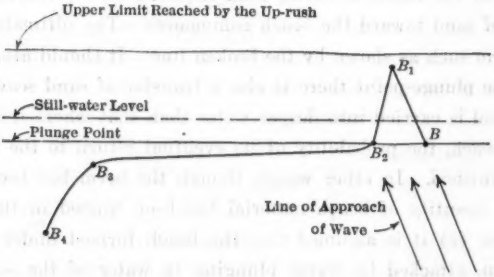

FIG. 7.—LITTORAL DRIFT IS MAINLY DUE TO UP-RUSH, BACK-WASH, AND UNDERTOW. A PARTICLE OF SAND AT B IS DISTURBED BY THE PLUNGE AND CARRIED BY THE UP-RUSH TO B_1, BY THE BACK-WASH TO B_2, AND BY THE UNDERTOW TO B_3 AND B_4.

When a wave strikes the beach from a diagonal direction (Fig. 7), the up-rush carries sand along with it in a diagonal direction. The back-wash also follows a diagonal course, but on the opposite side of the normal. The undertow frequently concentrates into a stream nearly parallel to the shore line, flowing out to sea at irregular intervals.

With the assumed conditions, a particle of sand disturbed by the plunge at B might be carried up the beach as far as B_1. At B_1, the force of the up-rush having been nearly expended, the particle is dropped until the returning back-wash has acquired sufficient velocity to set it once more in motion. The back-wash carries it as far as B_2, where the undertow takes charge. The latter is assumed to be nearly

parallel to the beach as far as B_2. At B_3 the undertow turns seaward, and the particle is carried into deep water.

The course followed by any individual grain of sand is an interrupted one, but, in the normal case, certain particles are at all times following each phase of the route shown in Fig. 7. The majority of the sand grains actually make many journeys up and down the slope, with a progressive movement to leeward, before they are finally taken to deep water by the undertow, or are carried to the semi-permanent uplands above the reach of the waves.

A study of the geology of Long Island indicates that during the glacial epoch enormous quantities of sand and gravel were deposited near the easterly end of the island, in a position where they were subject to wave attack. The prevailing direction of the waves has caused part of this material to be carried along the south shore for a distance of 100 miles, and has built up a nearly continuous beach along that shore.

The foregoing description of littoral drift applies to a continuous beach, and attributes the phenomenon of drift to wave action and undertow. It should be noted that any break in the continuity of the beach eliminates these forces. At such breaks, normally, there are tidal currents of considerable strength to be dealt with. Wave action keeps the bottom more or less agitated, and thereby assists the tidal currents in moving the sands.

It would seem that the question whether littorally drifting sand will be carried across an inlet to the leeward beach, to deep water outside, or into the harbor, is largely a matter of accident. In any event, inlets must result in a waste of beach-forming material, for there are strong tidal currents there which are capable of carrying the material far away from either the windward or the leeward beach.

Jetties and Groins.

As used by the writer, the term "jetty" will refer to structures reaching well out into deep water; the term "groin" will be applied to structures reaching only slightly beyond the low-water line. Wherever there is littoral drift, and jetties have been constructed, beaches have accumulated on the side from which the drift comes. Such is not the case with groins.

Referring to Fig. 7, it is noted that the littoral drift takes place largely below the still-water level. Above that level the sand move-

ment is principally up and down the slope, with only a small component parallel to the shore line. A jetty cuts off the littoral drift, both above and below the still-water level. A groin has little effect on drift due to undertow, and, so far as the drift above still-water level is concerned, a groin is effective for a limited distance only.

One effect of groins deserves serious consideration. Consider a groin so high that no water will over-top it. Such a structure (Fig. 8) will inevitably concentrate both the up-rush and the back-wash of the wave. With a low groin a lesser concentration is effected. It has been the writer's observation that, in the normal case, the berm will be cut back, and a valley will be formed in the vicinity of a groin.

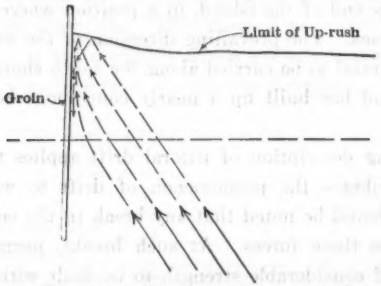

FIG. 8.—A GROIN INEVITABLY CONCENTRATES THE UP-RUSH AND THE BACK-WASH, AND DRIVES THE LITTORALLY DRIFTING SAND INTO DEEPER WATER THAN WOULD BE THE CASE ON AN UNOBSTRUCTED BEACH.

In the vicinity of an inlet, a training dike may be of great value in aiding the formation of a beach, even though it does not reach below the low-water line. At points where channels parallel to the beach (sometimes called swills) are formed, temporary dams across such channels may be of benefit, but, as the channels are transitory, permanent dams are unnecessary.

In order that littorally drifting material may pass a jetty, or a groin, it is necessary for it to travel into deeper water than would be the case on an unobstructed beach, and this deflection reduces the probability of its ever being returned to the beach. For these reasons jetties and groins must inevitably cause a wastage of beach material.

BULKHEADS.

When an engineer is required to build a bridge over a torrential river, he first searches for marks indicating the highest points reached by floods. Using the information thus obtained, he builds to resist

the forces that must be encountered. Similarly, when erecting structures along a beach, he should take note of the signs showing what part of the beach is transitory and what part is fairly stable. The level of the cocoanut grove at San Juan, Porto Rico, and of the sand hills at Long Beach, Long Island, previously mentioned, represent formations that have remained in their present location for many years, and, in the ordinary run of events, may be expected to last for many years. Who builds in front of these stable formations should build strong.

Confronted by a wide berm, such as that at Long Beach, Long Island, the property owner is tempted to erect some form of bulkhead in advance of the line of dunes. The strength of the bulkhead is proportioned to resist the final attack of the waves after most of their force has been spent in crossing the berm. An unfortunate combination of seasons may entirely remove the protecting berm, as it has been removed in former years, and the bulkhead will then be subjected to forces for which it was not proportioned. The result is that the sea takes back its own.

The effect on the berm and foreshore of such substantial sea-walls as are represented by the rip-rap walls guarding the Edgemere Club, the Manhattan Beach Estates, and the neck of land connecting Sandy Hook with the mainland, and of such substanital bulkheads as guard the tracks of the Central Railroad of New Jersey, from Highland Beach to Seabright, should be considered. It is often stated that such structures cause an erosion of the beaches in front of them. The writer believes that this erosion is much less than is commonly thought. The destruction of the berm is usually brought about by the undermining of the outer faces, as indicated in Fig. 6 (*a*), or by a rearrangement of the berm material, to obtain a higher berm of less width, as indicated in Fig. 6 (*c*). In the former case the quantity of material above mean low water is diminished; in the latter case it is increased. In both cases the width of berm is diminished.

Under certain conditions, the back-wash from a sea-wall may tend to undermine its toe by scouring out the bottom for a few feet in front of the wall, but the writer does not recall seeing a single instance of this kind along the many miles of bulkheads near New York City. To erode a berm like that at Long Beach, forces must work far to seaward and must carry the beach material to

deep water, or must, by littoral drift, take it to another part of the beach. A sea-wall would have no material effect on such forces.

The wall in front of the Manhattan Beach property has stopped the erosion of that property, and there is no evidence that it has caused a deepening of the water in front of the wall. There is at the present time a large shoal between Rockaway Inlet and the Manhattan Beach Estates. That shoal is moving steadily westward, and there is no reason to believe that the existence of the wall would prevent the shoal some day from making a contact with the Manhattan Beach property and forming a beach in front of the wall, should other conditions be favorable to such a movement.

The records show that the beach in front of a considerable portion of the sea-wall at the south end of Sandy Hook builds out and cuts away. The sea-wall limits the extent of the erosion, but does not prevent the formation of a new beach when conditions are favorable.

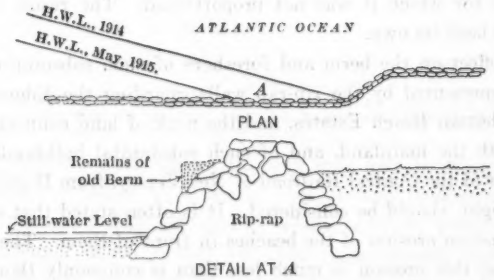

FIG. 9.—AT SANDY HOOK, N. J., THE REMAINS OF AN OLD BERM WERE SEEN WELL UP ON THE FACE OF THE SEA-WALL; BACK-WASH FROM THE SEA-WALL COULD NOT HAVE CAUSED THE EROSION UNDER WAY AT THE TIME.

In connection with this Sandy Hook wall, the writer on one occasion noted casually a condition that should have been carefully recorded and photographed. Its significance, however, was not realized until later. From memory, the conditions were about as shown in Fig. 9. The beach had eroded perhaps 200 ft. in less than a year. The inspection was made in May, 1915, during calm weather. Well up on the wall were the remains of the old berm, just as they had been left by the caving away of the outer part. The corners were sharp, and the caving may have taken place only a few hours before the inspection. It is highly improbable that the sand scarp would

have stood as it was for more than 2 or 3 days, yet the beach had already receded many feet from this particular deposit. The essential facts are that the beach in question was being eroded at a rapid rate by waves that were too small even to splash the old berm. Certainly, back-wash from the wall was not the cause of the erosion, nor was the erosion due to the action of storm waves.

A sea-wall having strength commensurate with its exposure will effectively protect the property in its rear. The location of such a wall, however, should be a matter for serious consideration. If placed so as to include permanently a portion of the temporary berms, the sand thus confined must be deducted from the supply that might otherwise be counted on for the maintenance of the beaches to leeward. The right of a property owner to take permanent possession of beach material temporarily deposited in front of his property may well be questioned. A fair compromise would seem to be that the improvement of the semi-permanent formations be encouraged, and their protection by any means not interfering with the littoral drift be permitted, but that no structures having in view the fixation of the materials composing the temporary berms should be authorized unless the work is on such a scale as to constitute a public improvement, taking care of the beach as a whole.

If used to protect an isolated portion of the water-front, a bulkhead should be placed at about the line separating the temporary berms from the semi-permanent dunes, or in rear of that line. If the protection of the beach as a whole is undertaken, the bulkhead, sea-wall, or detached breakwater may be placed so as to include the temporary as well as the more permanent formations.

It should be understood that the construction of a detached breakwater or a sea-wall enclosing the berms will effectually stop the littoral drift along that frontage until a new beach has been formed outside of the sea-wall or breakwater. If there are beaches to the leeward the effect on them may be disastrous.

Detached breakwaters should afford protection to the beaches in front of which they have been placed. They should create along those beaches conditions similar to those existing in protected bays and harbors. So far as the protected beaches are concerned, rapid changes due to wave action will be done away with, and the beaches may be extended by dredging and filling if desirable.

Conclusion.

It would appear that along each mile of open beach there is a constant transfer of sand from the shore to deep water. When littoral drift is the source from which the supply necessary to maintain the beach is obtained, the quantity of material brought to the section must, in order to maintain the beach, be at least equal to the material carried into deep water plus that carried away by littoral drift.

Assuming a section of beach where the littoral drift is exactly sufficient to replace the wastage, no checking of the sand at any point will benefit the beach as a whole. The valuable part of water-front property is the part corresponding to the level of the cocoanut grove in Fig. 5, but the value of this portion is somewhat dependent on the existence of a sufficient berm at a lower level. Uplands may be protected by sea-walls and bulkheads, but bathing beaches must necessarily lie outside of such structures.

The writer knows of no means by which exposed sandy beaches for surf bathing may be preserved, except by feeding fresh beach material to them as rapidly as the old material is carried away. The rate of growth of Rockaway Point and Long Beach would indicate that many millions of cubic yards per year are required by the beaches of the south shore of Long Island to counterbalance the demands of the littoral drift. There are no data, so far as the writer is aware, by which the quantity of sand carried annually into deep water can be approximated. At all events, it is safe to say that, if the natural supply of beach maintenance material was to be cut off, any attempt to make up the deficiency by dredging or other artificial means would be a stupendous undertaking.

Along the New Jersey shore north of Asbury Park there remain to-day only a few isolated temporary berms. Along most of that shore the waves are eating into the semi-permanent formations or are battering against the bulkheads. It would seem that the only salvation for many sections of that beach lies in the construction of sea-walls of sufficient strength to combat the waves until such time as new berms are formed, if such time ever comes.

A study of the littoral drift on the south shore of Long Island and the disastrous results to certain beaches that have followed tem-

porary stoppages of that drift would be well worth while. The stoppages in the past have been brought about by natural causes, but the works of Man will play an important part in the future, and we may well take warning while there is yet time and see to it that the interests of the millions who annually visit the beaches of the south shore are properly safeguarded.

DISCUSSION

Mr. Haupt.

LEWIS M. HAUPT,* M. AM. SOC. C. E. (by letter).—This interesting paper is limited to the vicinity of the New York entrance, but the principles involved are of general application, with local modifications, so that the writer ventures to call attention to certain features which seem to him somewhat obscure, in the hope of leading to a more definite application of the principles to general practice.

The literature of the subject is prolix, and the publications of the Society, the Institution of Civil Engineers of Great Britain, and numerous other technical societies, contain elaborate discussions of both theory and practice; yet there seems to be room for further analysis, at least of the application of the theory to definite localities, as the results desired are not always attained.

Omitting, for the sake of brevity, the theoretical considerations, as being "somewhat idealized" as to the paths described by the forces which transport the drift, it will be more important to consider the facts as recorded by Nature and, from them, mould our conclusions.

The instrumentalities available for reclamation are jetties and groins, bulkheads and sea-walls "properly applied". This is the crux of the matter, for, in many instances, bulkheads and jetties have proved more injurious than beneficial, and as the local conditions are subject to frequent changes, due to occult cosmic forces, it is very difficult to adjust a permanent structure so as to give satisfactory results under the composite conditions, which is all that the engineer can do.

As to "jetties and groins", a distinction is made, based on their relative lengths, but it would seem better to limit the term to the word "jetty", as a projection from the shore across the strand, than to "groin or groyne", the angle formed by the intersection of two surfaces.

The writer believes that the statement as to their effects, namely, that they "must inevitably cause a wastage of beach material", should be taken *cum grano salis,* for, in the locality in question, short jetties have had a very decided effect in building up the beach without apparent injury to the leeward properties; for instance, at Far Rockaway two jetties (Fig. 10) were erected, about 4 years ago, concerning which the parties say: "The work is highly gratifying as we have gained at least 500 ft. in the width of beach and raised the crest of it away above the top of the piles forming the jetties." The writer is informed, also, that similar jetties built at Long Beach are likewise buried out of sight.

The extensive works now under contract to protect the tracks of the Central Railroad of New Jersey at Seabright, consisting of some thirty jetties reaching out 200 ft., have collected some of the drift at the southerly end, but have not recovered the original low-water line, which was more than 600 ft. out a few years ago. These jetties sup-

* Cynwyd, Pa.

FIG. 10.—HOOKED JETTIES NOW BURIED UNDER THE DEPOSITS WHICH THEY HAVE MADE.

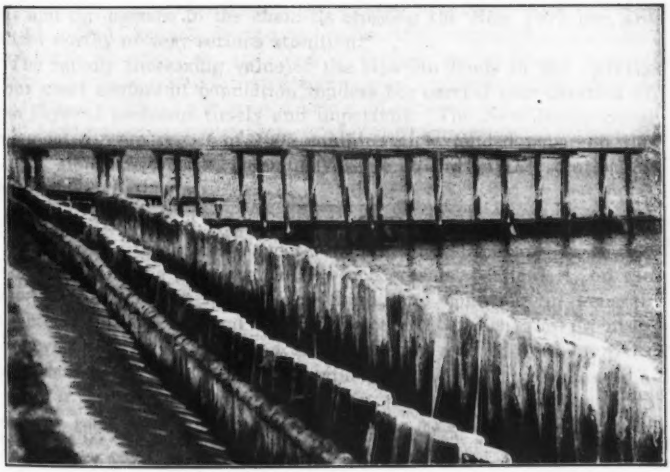

FIG. 11.—REINFORCED CONCRETE JETTY, LONG BRANCH, N. J., FEBRUARY, 1916. BULKHEAD DENUDED AND BACK-FILLING GONE.

plement a heavy bulkhead filled with stone, and this, in severe storms, is scaled by the breakers, which fall over on the track and destroy it. Mr. Haupt.

The influence of the prevailing winds must also be carefully considered, for it is a factor in the accumulation of material, independently of the drift carried by waves and currents. The low, short jetties at Belmar, N. J., during the winter of 1915-16, were completely covered by this wind-driven sand, and under normal conditions they do arrest the northwardly moving drift in the southerly groins, filling them to the crests and traveling over.

Many of the bulkheads along the New Jersey coast have been denuded entirely of their back-filling, and have been further protected by lines of stockades filled in with stone, yet they have not recovered the lost ground, nor do they protect the properties in their rear from the violence of the waves, as has been exemplified so fully by the storms of the past few years, so that it would seem to be unwise to place much stress on this form and location of defensive works. Fig. 11 shows a reinforced concrete jetty at Long Branch, N. J., in February, 1916; the bulkhead was denuded and the back-filling gone.

The statement that "the only salvation for * * * that beach [Asbury Park] lies in the construction of sea-walls of sufficient strength to combat the waves until such time as new berms are formed, if such time ever comes", would seem to be somewhat discouraging, were it not for the fact that, up to this time, no dependence has been placed on "sea-walls" but only on short spur-jetties.

The causes of the temporary stoppages of the drift along the south shore of Long Island, as well as the quantitative movements of the drift and the menace to the channels crossing the New York bar, are matters worthy of very serious attention.*

The rapidly increasing value of the riparian lands in the vicinity of our great centers of population renders the careful consideration of these physical problems timely and important. The New Jersey State Geological Survey report of 1905 contains an extended paper on the changes along that coast which may serve to aid in the solution of these complex problems.

CHARLES H. HIGGINS,† M. AM. SOC. C. E. (by letter).—This paper is most interesting, and the writer congratulates the author on his lucid analysis of the phenomenon of beach erosion, particularly on the coasts of New Jersey and Long Island, and confirms, in general, his observations on littoral drift. However, between the premises laid down as to littoral drift and the conclusion, reached by the author, that: "damage * * * must inevitably result to the beaches as a Mr. Higgins.

* Some allusions to these matters may be found in the *Journal* of the Franklin Institute for February, 1905, and in the *Proceedings* of the Brooklyn Engineers' Club in a paper on the "Reclamation of Coney Island."

† New York City.

Mr. Higgins.

whole if the erection of structures that interfere with littoral drift is allowed to continue", there is a wide gap, which it does not appear to the writer has been logically crossed, and which is certainly not in accord with his observations.

The writer has described* the theory and construction of a system of groins or jetties, constructed at Asbury Park, N. J., under his supervision, 9 years ago, and the results obtained.

Fig. 7 illustrates thoroughly the typical action of waves on a sand beach. In this problem of erosion on a sandy coast, though the masses dealt with are tremendous, the unit is very small, namely, a grain of sand; and, just as the unit of a great army is a single man, and the movements of that army, as a whole, are dependent on the behavior of each of the units, so, if the grain of sand is controlled, by extension the mass may be controlled.

The phenomenon of littoral drift apparently results when the grains of sand are not moved by the waves directly fore and aft, but are sawed along, as indicated by Fig. 7. B_2 is the critical point, for when the line containing the series of points, B_2, moves toward the shore, the observer at once remarks that we are losing beach. On the other hand, when the line moves seaward, beach is made.

Now, the purpose of a system of groins may be single or twofold; that is to say, it may be designed to prevent this critical line, marked "Plunge Point" on Fig. 7, from moving shoreward, in which case the groins end on this particular line; or it may be intended, also, to force this critical line farther out, and thus increase the width of the beach, in which case the ends of the groins extend beyond B_2, thus forcing the shore current farther out, and consequently making beach. An important consideration in such a design is the distance between the several groins. By Fig. 7 the author has indicated clearly the typical path of a grain of sand by lines which form the figure of a saw tooth, B-B_1-B_2. A low groin to the left of B and another to the right of B_2 would, by interrupting this movement, prevent this sawing away of the beach.

The critical line, which the author has named the "plunge point", is really the fighting line between land and sea—the first-line trench, as it were—and as this advances or recedes, a gain is made by one or the other of the contending forces.

Considering the shore as a whole, it is hard to conceive what damage can be expected to result from fixing this "plunge point" line, either where it may be in the particular year the groin system is built, or a few feet or even a few hundred feet farther out. The phenomenon of littoral drift proceeds uninterruptedly on the new line. The author, on the other hand, seems to prefer a bulkhead constructed apparently

* *Engineering News*, April 16th, 1914.

along the line on Fig. 7 marked "Upper Limit Reached by the Uprush". Where bulkheads have been built without a groin system in front, it has usually resulted in the "plunge point" line moving back to the toe of the bulkhead; in other words, the beach is lost; the shore, however, is maintained as long as the bulkhead remains intact. Mr. Higgins.

Now, the only apparent difference in effect on littoral drift is whether that drift occurs along a line through B_1 or along a line somewhat in advance of B_2. The only difference in material, added or subtracted, is the beach between the two lines; and a matter of a few hundred feet, in dealing with an adjustment in masses like sea and land, contains such a comparatively minute quantity of material as to be negligible in considering the total volume.

In very many cases, the protection of the shore, without maintaining a beach, is not sufficient; for example, at Asbury Park, with its mile of ocean front, it is of the greatest importance that a broad sand beach be maintained, and, in general, a shore line with a beach in front of it is preferable to one in which simply a bulkhead marks the limit between land and water. It should be borne in mind that such coasts are developed or used for summer colonies. There are also economic elements entering into this problem. A bulkhead to resist the direct and unimpeded action of the ocean is no trifling affair.

It is the writer's opinion that, in most cases, where shore front for residence purposes is involved, economy, utility, and attractiveness are all best served by a system of construction designed to hold what the author names the "plunge point" line at some distance in front of the shore line—that is to say, dry land—and that this may be accomplished by a properly designed and constructed system of groins or jetties, with a light bulkhead in the rear to prevent wash, the bulkhead being protected from the direct attack of the sea by the beach, which in turn is preserved from erosion by the system of jetties or groins.

It is noteworthy that the author limits his discussion of the New Jersey Coast to that part of it above Asbury Park. The writer is of the opinion that, if the coast above Ocean Grove and Asbury Park received a treatment similar in principle, a similar satisfactory result would be obtained and at a minimum expense.

A massive bulkhead seems to appeal to the imagination, just as a masonry fort does; but, where the impressive fort fails, the simple trenches prove effective. Thus, in preventing the advance of the sea, the low groins hold the line under conditions where the massive bulkhead is smashed to bits.

ALLEN HOAR,* JUN. AM. SOC. C. E. (by letter).—The author of this valuable paper is to be commended on the manner in which he has brought this serious and often difficult problem of beach control to Mr. Hoar.

* Pasadena, Cal.

Mr. Hoar. the attention of the Profession. The paper sets forth clearly and concisely many of the difficulties to be encountered in work of this kind, and points out the necessary investigations to be made before such work can be planned with any certainty of ultimate success. It should be a warning to those who would undertake the planning and building of beach structures without first making careful and thorough investigations extending over a sufficient period of time, and taking into consideration all probable weather conditions. This, unhappily, has not always been done, and many unnecessary failures have resulted.

The writer has been fortunate in being able to make a close study of the beach conditions at Long Beach, Cal., for the past 5 years, and has watched with interest the encroachment of property owners on the waters of the Pacific Ocean along that section known as the West Beach. In this instance, the beach adjoining property has become valuable as a desirable location for hotel-apartment houses and other tourist accommodations, but, as this particular piece of property is just a narrow strip facing the Pacific Ocean on the south and backed up on the land side by high bluffs and the Pacific Electric Railway yards, offering no suitable approach from that direction, it was necessary to build an approach from the east along the beach front. This was also deemed desirable for use as a promenade. For this purpose, and to add to the attractiveness of the beach front property, it was decided to build a wide concrete walk and bulkhead.

The error in judgment here and the difficulties to be met in carrying out the plan adopted were due to the fact that, for the greater part of its length, the southerly line of this property was only a few feet back from the ordinary high-water line, and the walk as constructed, from the property line south, encroached to a considerable extent below the high-water mark and still-water level. The consequence of this has been that, during extreme high water of spring tides, whether accompanied by heavy storms or not, great damage is done to both the bulkhead and walk, and the beach lying in front of the bulkhead is destroyed. Each year since its construction some portion of this bulkhead and walk has been torn out and has had to be rebuilt, and, in fact, it has never been possible to finish the construction at the western end, this section of the work having been destroyed before completion time and again at each attempt.

The bulkhead at and supporting the outer edge of the walk consists of a single row of reinforced concrete sheet-piles, about 6 by 12 in. in section, and from 14 to 16 ft. in length, cast tongue-and-groove fashion. The reinforcement consisted of four vertical rods, one in each corner of the pile, and projecting several feet above the head of the pile for anchorage into the parapet wall to be built after the piles had been placed. The piles were raised by a light pile-driver mounted on skids, and jetted and driven through the sand to penetrate

a layer of clay at a varying depth of from 12 to 14 ft. below the surface. After the piles had been driven to place, a concrete cap was cast in place along the top of the row of piling, and the bulkhead was then back-filled to the level of the cap. The walk, of 6-in. concrete, was then laid, the outer edge being supported on the cap and the remainder resting on the back-fill. Along the outer edge of the walk and over the row of piling a reinforced concrete parapet wall was next cast in place. This wall was built in panels and reinforced horizontally by rods running through its base and through its coping. It was reinforced vertically by the rods which were left projecting above the tops of the piling, serving to anchor it firmly to its base. This construction would have been adequate under all ordinary circumstances, if the bulkhead had been placed at or back of the high-water line, but, placed where it is, in from 1 to 2 ft. of water at ordinary high tides, it is subject to severe impact which becomes terrific with the force of the larger breakers accompanying stormy weather. Mr. Hoar.

The construction of this bulkhead has had a very marked effect on the destruction of beach in front of it. This is undoubtedly because the bulkhead is only a few feet shoreward of the plunge point of the incoming breakers, thereby limiting the extent of the up-rush and its sand-carrying power to a point where the power of the back-flow is predominant; and, in the case of unusually high water, when the plunge takes place almost on the bulkhead, the force and action of the plunge is felt clear down to the sand, and results in excessive scour and erosion. This is due to an almost entire absence of back-flow at this point, and, therefore, instead of spiraling over a comparatively strong back-flow, as is usual, the plunge is carried right to the bottom.

The conditions here are peculiar, in that there is practically no littoral drift of sand or other beach-building material, and therefore no method can be advanced for the rebuilding of the beach by bringing the natural forces into play.

The sand composing this beach is very fine, and contains a very large percentage of extremely light material. The surface of the sand along the beach slopes normally about 2 ft. per 100 ft. to a point about 300 ft. from the high-water line, and from this point it shelves off gradually until it strikes an almost vertical bank about 600 ft. off shore, where the water has an average depth of about 35 ft. There exists just beyond this bank an off-shore current flowing westward, although with no very great force except in case of storm.

The light character of the beach sand allows it to be set in motion by even slight agitation of the breakers, and, when acted on by the large swells raised by a storm, this light material is carried away out by the undertow until it reaches the off-shore current, by which it is carried out to deep water. During calm and low tide much of this

Mr. Hoar. sand is carried only to the outer breaker line where it is again picked up, carried shoreward and deposited on the beach by the up-rush. This is shown by the fact that during calm weather, when the breakers are small, the beach builds up very flat, and, under the influence of the large swells after a storm, it is rapidly cut away between the high- and low-water lines, leaving a comparatively steep slope.

The tidal drift along this beach is from east to west, but the inshore drift is so slow that it is not of the slightest value in transporting sand to build it up.

From the foregoing it can be understood that, in this case, the large sand-laden breakers accompanying heavy storms cannot, because of the location of the bulkhead, aid in the preservation of the beach by building up a new berm, as is the general result as pointed out by Mr. Dent. On the contrary, erosion is accentuated, and a considerable portion of the sand put in motion is transported by the heavy undertow to the off-shore current, where it is lost to the beach for all time.

Mr. Schwiers. F. WILLIAM SCHWIERS,* ASSOC. M. AM. SOC. C. E.—The speaker has had some experience on this subject on the south Long Island shore, and also on the New Jersey shore; and has read considerable on the topics referred to. The Library of the Society contains some volumes written by Mr. Case or Mr. Allanson-Winn, describing the Case system of low groynes. The speaker believes that this system—where its use is feasible—is the best method of shore protection. Briefly, it consists of low barriers, built on the beach, and started below the low-water line. These barriers catch the drift carried by the along-shore currents and build up the beach. As the latter is built up, the groynes are continued shoreward on the proper incline, which corresponds to an elliptical curve, and has been termed the ellipse of repose. The waves ascend the inclined surface until they have spent their energy, and then recede harmlessly. During storms the low groynes are entirely submerged, and are protected by the overlying water.

The Case system has been used extensively in England, but is not adapted to the Jersey shore, because the property owners there have encroached too far on the ocean. In some cases bulkheads have been built even beyond the low-water line, so that no beach is visible at low tide.

The method of protection used along the Jersey shores is timber and pile bulkheads, parallel with the beach, behind which beach sand has been filled in, and low jetties running seaward. The jetties, generally speaking, are low structures entirely submerged during heavy weather, their purpose being to build up the beach in a manner similar to the Case groynes. The destruction of bulkheads takes place during

* New York City.

very high tides accompanied by storms from certain directions. On the south Long Island shore erosion takes place during northeast storms and on the Jersey coast during storms from the southeast. The heavy waves, striking the bulkhead, are deflected upward and downward, creating a semi-fluid mass of the beach material at the foot of the bulkhead. If the sheet-piling has not sufficient penetration, the material back of the bulkhead soon becomes a semi-fluid mass and escapes under the sheeting; this leaves the bulkhead without support, and its destruction rapidly ensues. To support the bulkhead against this contingency, during late years, a second row of brace-piling has been driven about 20 ft. back of the bulkhead, to which horizontal brace logs are attached and connected to the bulkhead piling several feet from the top. This method has been fairly successful, provided there has been sufficient penetration for both the sheet-piling and the round piling. There is sufficient elasticity in this construction, in connection with the material back of the bulkhead, to absorb the shock of the waves. Heavy masonry bulkheads have not been successful along the Jersey shores, and they are not advisable unless an absolutely firm foundation can be obtained and the footing of the wall can be protected from scour by sheeting with deep penetration. Mr. Schwiers.

The situation on the Jersey and Long Island shores is probably aggravated by littoral currents created by the flow of the Hudson. This river, flowing into the ocean, creates shore currents flowing northward along the Jersey coast and westward along the Long Island coast, eroding the southern Jersey shore and eastern Long Island shore, and carrying the material northward and westward, respectively, thus accounting for the formation of Sandy Hook and Coney Island. These littoral currents are reinforced by storms from certain directions, *viz.*: southeast on the Jersey shore and northeast on the Long Island shore; and when both these conditions are coincident with an abnormally high tide, great erosion and destruction ensue.

A. W. Buel,* M. Am. Soc. C. E.—In his discussion, Mr. Schwiers has referred to the Case system of groynes which has been used with great success in several places in England, on both the south and east coasts. These groynes are very low, sometimes only a few inches above the beach, and never more than 18 in. They are arranged so that, as the beach is built up by catching the littoral drift, additional planks can be put in, the groynes thus being raised from season to season. There are records of some places on the English coast where the beach has been built up as much as 8 ft. in a few seasons, and extended out several hundred feet. Mr. Buel.

* New York City.

Mr. Buel. Mr. Case almost invariably had a very low wall at the top of his groynes, that is, at the shore line above high water, and, generally, he used a pavement connecting the beach or the groynes with the sea-wall which he made elliptical. He adopted the elliptical curve as that most nearly agreeing with the angle of repose on the beach under the conditions that exist in those parts of England.

Mr. Allanson-Winn has written several papers* in which he describes the results obtained with Case groynes, and suggests an addition or improvement to the system, consisting of what amounts to extensions of the groynes to a connection with the sea-wall or bulkhead. This extension, from high-water line to bulkhead, is curved in plan. On all the beaches along the New Jersey coast, and also on Long Island, the jetties or groynes are what would be described as high groynes, when compared with the Case system. They are far more substantial and expensive structures than those described by Mr. Case and Mr. Allanson-Winn and, for this reason, are probably less efficient. The very low Case groyne builds up a smoother, more uniform beach than the jetties used on the Jersey and Long Island shores.

The Case groynes were built in England at a cost of about 10 shillings per lin. ft., and Mr. Allanson-Winn's curved extension, connecting the groynes with the bulkhead wall, does not cost more than £1 per lin. ft.

Mr. Cresson. B. F. Cresson, Jr.,† M. Am. Soc. C. E. (by letter).—The question of beach protection raised in this paper is one of great importance to the State of New Jersey, and for several years the condition of the beaches has been under observation by the New Jersey Harbor Commission and, its successor, the New Jersey State Board of Commerce and Navigation.

Particularly was this matter earnestly studied during the winter of 1914-15, when great damage was done to the northerly New Jersey coast between Long Branch and Sandy Hook. The damage was especially great at Seabright, but serious erosions occurred along the Southern New Jersey coast, notably at Longport and Stone Harbor. Plans were prepared by the New Jersey Harbor Commission in 1915 indicating a form of coast protection and urging a comprehensive plan to be adopted in order that the beach might be saved and built, instead of being damaged by the various types of coast protection which have been placed without reference to each other and to a general plan. Each individual property owner usually had his own plan prepared and his own structures built without respect to his neighbor, and the damages that were done were due, at least partly, to the lack of a general study and a general plan. This is notably the case in the vicinity of Seabright.

* *Minutes of Proceedings*, Inst. C. E.

† Jersey City, N. J.

Mr. Cresson.

The writer has read this paper with much interest and considers it a valuable contribution to the somewhat meager literature on this subject, but is compelled to take exception to some of the author's conclusions.

The opening paragraph of the paper states: "The object of this paper is * * * to emphasize the damage that must inevitably result to the beaches as a whole if the erection of structures that interfere with littoral drift is allowed to continue", and, supporting this statement, the author says:

"In order that littorally drifting material may pass a jetty, or a groin, it is necessary for it to travel into deeper water than would be the case on an unobstructed beach, and this deflection reduces the probability of its ever being returned to the beach. For these reasons jetties and groins must inevitably cause a wastage of beach material."

Although this may be the case with high jetties or groins, the writer has observed that it does not apply with low groins. Where low groins are used, and where there is a drift of the sand, the tendency is to build up a beach and numerous instances show it. Groins, 1 or 2 ft. above the level of the sand, will allow the current to pass over them, and, in doing so, retard the speed of the drift; then the sand in suspension will be deposited on both sides of the groin. There are numerous instances to show that this is the case.

The groins which the Central Railroad Company of New Jersey has recently built in the vicinity of Monmouth Beach have already commenced to gather sand, and, in conjunction with a sloping bulkhead, appear to be the most effective method of reclaiming the beach and stopping erosion.

The writer can scarcely agree with the following conclusion by the author:

"It would seem that the only salvation for many sections of that beach lies in the construction of sea-walls of sufficient strength to combat the waves until such time as new berms are formed, if such time ever comes."

The writer believes that a combination of low groins and a bulkhead or sea-wall with a sloping, curved, or broken face, so that the receding waves may not scour at the toe of the wall and carry the sand to sea by the undertow, is the most effective method of gathering beach and of protecting the foreshore. Neither groins alone, nor bulkheads alone, will accomplish this result, in the writer's judgment, under conditions such as exist along the New Jersey coast.

Instead of attempting to combat the waves by the strength of a heavy sea-wall, the writer believes it is far better to attempt to guide the forces of Nature by permitting the sand to collect in front of the bulkhead by the placing of low groins; the sand itself will then form a protection for the bulkhead.

Mr. Dent.

ELLIOTT J. DENT,* M. AM. SOC. C. E. (by letter).—In the first paragraph of the paper, its application was limited to that portion of the New Jersey shore north of Asbury Park. Asbury Park should have been included, as that beach was visited on several occasions, and the remarks and conclusions are applicable to it.

The discussion has been directed principally toward the writer's remarks in regard to groins and the detrimental results that must inevitably result if structures interfering with the littoral drift are erected along the beaches under consideration. Before taking up the discussion in detail, a few additional general remarks in regard to littoral drift are necessary.

Littoral drift is generally spoken of as though it were of constant magnitude; beaches are referred to as being in equilibrium, due to the fact that the littoral drift brings to them as much material as it takes away. As a matter of fact, no such equilibrium will be found to exist along beaches around New York City; such beaches undergo erosion for a period of years, and subsequently there is a period of accretion; the growth and denudation of the beach occur in what may be styled "cycles". The cause of these cycles is apparently the progress of sand waves along the shore. If the point where the temporary berms are widest is called the crest of a sand wave, and the point where the semi-permanent dunes are subjected to attack is called the trough, two such waves were in evidence during the summer of 1915. In one case the trough of such a wave was traveling along the sea wall at the south end of the Sandy Hook Military Reservation, while wide berms, corresponding to the preceding crest, might have been seen a mile or so farther north. At Long Beach, temporary berms of considerable width existed in front of the boardwalk and for a distance of perhaps 2 miles to the east; the berms then disappeared, and, for a considerable distance, the sea was making a direct attack on the semi-permanent dunes; still farther east, in the vicinity of Point Lookout, wide berms were again in evidence.

The material comprising the temporary berms is loose and friable, but when they have been removed, the remaining beach material along the New Jersey shore will be found to contain a large percentage of gravel, which offers considerable resistance to further erosion. Whatever may be the cause of the added resistance, the beaches along the Long Island shore appear to be much harder and much less susceptible to erosion after the temporary berms have been removed than they are while such berms are in existence; the temporary berms are loose under foot, and walking along them is a considerable labor, while, at the same elevation, where the berms have been removed, the beach will be found to be fairly compact and the walking easy.

---

* Little Rock, Ark.

Mr. Dent.

Suppose, for example, that an engineer has been called on to design works for the protection of a beach 1 mile in length, and that, due to the passage of the trough of a sand wave, this frontage has been subjected to an attack. Suppose, further, that the crest of a new sand wave is approaching. If no interests other than those of this particular mile of beach are to be considered, it may be feasible to stop the passing of the littoral drift by the erection of a jetty of such height and length that no sand will pass around or over it until the windward beach has grown up to the desired extent. The cove formed on the windward side of this jetty having been once filled by the littoral drift, and the shore line having advanced to the end of the jetty, the drifting sand would proceed around its end, and would eventually travel along the leeward beaches as though no obstruction had been created.

For the protection of such a beach, Mr. Higgins proposes the use of groins. According to him, such groins will cause the line marked "Plunge Point", on Fig. 7, to advance seaward, and the other lines to advance a similar distance. Mr. Higgins states that the quantity of material required to extend the beach "a few hundred feet" is "negligible".

Conceding for the moment that the line marked "Plunge Point" and the other lines of the beach may be moved seaward by the construction of groins, the following propositions will logically follow:

(*a*).—The material used to build up the beach is the same in the case of the jetty as in the case of the groins.

(*b*).—On account of the increased depth of the reclaimed areas, as compared with the depths over the areas that would have been reclaimed by the natural berms, the former area will be less than the latter.

(*c*).—Fixation of the drifting sand to reclaim the artificial beach will postpone for a corresponding period the date when the leeward beaches will receive a new supply of material.

(*d*).—Dependent on the particular location, the length of beach benefited may be less than that injured.

If the drift was passing in a steady stream, the erection of a jetty or of a system of groins (still assuming for the sake of argument that a system of groins will check the littoral drift) would result in the creation of an artificial trough, and the leeward beach would be subjected to the attack which always accompanies the passage of such a trough. Other conditions might be assumed, but the conclusions would be in no wise modified.

Any structure that stops and retains the littorally drifting sand in front of any particular property must inevitably induce an attack on the leeward property. It is an extraordinary fact that though the stoppage of the littoral drift by a jetty is so generally recognized as

Mr. Dent.

being detrimental to the leeward beaches, it is claimed, nevertheless, by numerous writers, that the stoppage of the same drift in front of the same property may be effected by the use of groins without damaging the leeward property.

Turning now to the questions raised as to whether groins will actually check the littoral drift and cause an accretion to the beach in one case, or whether a system of groins will retard the erosion of an existing beach in another case, it will be well to examine into the results actually visible along the Long Island and New Jersey shores.

The sea-wall at the south end of the Sandy Hook Reservation has been referred to several times. Since the paper was written, it has been learned that, in 1901, six timber groins, of the type usual along the New Jersey shore, were built near the north end of that wall. The writer visited the locality several times during 1914 and the first half of 1915, and the groins were buried so completely that their presence was not suspected. The fact that, after the erection of the groins, the beach was extended seaward until they had been completely buried so that they were no longer able to affect in any manner the growth of the beach, and the fact that the growth of the beach did not stop there, would indicate that the groins were not the primary cause of the accretion. The alignment of the beach would have led to a similar conclusion if the existence of the groins had been known.

In May, 1915, erosion was taking place along the face of this sea-wall, as described on page 1802. The trough of a sand wave was traveling north along the shore. As this trough continued its northerly course, it encountered the first groin of the group. The existence of the groin did not stop the erosion. By November two groins had been exposed for their entire length and a part of a third one was bared. The writer has no information as to what has occurred since 1915, but here is a case where there is strong presumptive evidence that the growth of the beach was due to causes entirely independent of the erection of groins, and there is positive evidence that the groins were impotent, so far as the preservation of the beach was concerned, when conditions had so changed that a period of erosion was due.

Mr. Haupt states that jetties similar to the one shown in Fig. 10, at Long Beach, Long Island, are now "buried out of sight". The writer in 1915 walked the entire length of Long Beach, from Point Lookout on the east to East Rockaway Inlet on the west, and noticed no evidence of their existence. As in the case of the Sandy Hook groins, the fact that the Long Beach structures were completely buried creates a presumption that the growth of the beach was due to some cause other than their construction. Mr. Haupt has described* certain shore protection works at Edgemere, Long Island, and has presented a map showing that shortly after the erection of these structures there

* *Proceedings*, Brooklyn Engineers' Club, 1913.

was a material growth along the corresponding frontage. The same map, however, shows that the growth of the beach, along the frontage which it was aimed to protect, was not measurably greater than that of the beach during the same period for a considerable distance east and west of the protected section. Is this not presumptive evidence that the accretion noted was due to causes entirely independent of the erection of the works designed by Mr. Haupt? Mr. Dent.

The hooked jetty shown in Fig. 10 was by no means buried at the time the photograph was taken. If any accumulation took place after its erection, no evidence has been presented to show that it was due to the presence of the structure. The evidence furnished by this photograph would indicate that there was a considerable depth of water at the outer end of this hooked jetty, and the photograph does not show any materially greater deposits on the windward than on the leeward side.

Mr. Higgins has described as follows, the work that he advocates for the New Jersey shore above Ocean Grove and Asbury Park:

"It is the writer's opinion that, in most cases, where shore front for residence purposes is involved, economy, utility, and attractiveness are all best served by a system of construction designed to hold what the author names the 'plunge point' line at some distance in front of the shore line—that is to say, dry land—and that this may be accomplished by a properly designed and constructed system of groins or jetties, with a light bulkhead in the rear to prevent wash, the bulkhead being protected from the direct attack of the sea by the beach, which in turn is preserved from erosion by the system of jetties or groins.

"* * * The writer is of the opinion that, if the coast above Ocean Grove and Asbury Park received treatment similar in principle, a similar satisfactory result would be obtained and at a minimum expense."

Mr. Cresson favors the same system.

Long Branch is situated along the shore referred to by Mr. Higgins, and, in Fig. 11, Mr. Haupt shows structures of the type recommended, namely, a system of groins backed up by a bulkhead. The illustration shows that the groins have not held the plunge point at a distance from the bulkhead, and that no protecting beach has been built up to prevent the direct attack of the waves on the bulkhead. Fig. 11 is typical of what may be seen at many points along the New Jersey shore. To be sure, Mr. Higgins limits his claims to a "properly designed and constructed system of groins or jetties", and Mr. Cresson limits the height of his groins to 1 or 2 ft. above the surface of the sand, but the average engineer is unable to find any essential difference between the structures now existing along the New Jersey shore and the structures advocated. Some explanation as to why existing structures have failed should be forthcoming before we are asked to place our faith in additional work so nearly like the old

Mr. Dent. that we are unable to see any essential difference. Mr. Haupt calls attention to the fact that, in many instances, "bulkheads and jetties have proved more injurious than beneficial".

At Sea Gate, on the Long Island shore, a system of groins backed up by a light bulkhead proved no more successful than the one at Long Branch illustrated in Fig. 10. As a result of damage done during the winter of 1914-15, an offshore breakwater was started during the summer of 1915 for the better protection of the Sea Gate property. Mr. Haupt has referred to two jetties built at Far Rockaway about 4 years ago. Concerning these jetties it is stated that the work is highly gratifying, as at least 500 ft. in width of beach has been gained, and the crest of the beach has been raised away above the top of the piling forming the jetties. As stated previously, when the growth of the beach is such as to bury out of sight the groins or other protection works, it is, to the writer, presumptive evidence that the cause of this growth is due to some condition entirely independent of the existence of the structures. During the winter of 1914-15, Far Rockaway and Edgemere were severely battered by storms. During the summer of 1915 several wrecked groins in this vicinity were visible, but the only work in sight which appeared to be protecting successfully the property which it was supposed to guard was the rip-rap bulkhead around the Edgemere Club. In 1910, there were at least ten groins or jetties in that vicinity, but, with the evidence before them, the land-owners of Edgemere decided, in the summer of 1915, to construct an off-shore breakwater for the protection of their property. The work was started during the same summer.

The foregoing refers to the general effect of groins, and the writer's conclusion has been that they are totally unable to build up a denuded beach or to prevent the denudation of an existing beach. It remains to examine more closely into the effects visible in the immediate vicinity of the numerous existing groins along the beaches under consideration. At the same time there will be discussed exceptions taken by Messrs. Haupt and Cresson to the writer's statement that, by forcing the littorally drifting sand into deeper water than it would reach under natural conditions, jetties and groins must inevitably cause a wastage of beach material.
